ABSTRACT

The time-scale representation of the Morlet wavelet transform is studied on characterizing NMR signals. By an analytical analysis and simulations, the wavelet shows a satisfactory performance even when a baseline, an additive Gaussian noise and a solvent are presented in the signals. It can also cope with non-Lorentzian lineshapes which commonly occur due to inhomogeneous distribution of molecules in a substance. These results signify the Morlet wavelet transform as a potential tool to quantify *in vivo* NMR signals.

1. INTRODUCTION

A nuclear magnetic resonance (NMR) signal is acquired when the nuclei in a substance are excited by a radio frequency pulse, and re-radiated. This results in an exponential decaying sine wave, which has a so-called Lorentzian lineshape in the frequency domain. The frequency of the signal is dependent upon the nucleus and therefore typical to each substance. The amplitude in the time domain, i.e. the area in the frequency domain, depends on the amount of those nuclei, which can then relate to the concentration of the substance [1]. Therefore, a good quantification technique is essential for the interpretation of the NMR signals.

For this purpose, a number of techniques have been proposed to use in both time or frequency domains (see [2, 3]). There also exists the wavelet transform which is known for its time-scale representation. Analyzing in the two domains makes it beneficial to the Fourier transform which gives only spectral information. In addition, a small perturbation of a signal will result in a small, local modification of the wavelet transform.

Among several categories of the wavelet transform, the continuous wavelet-based techniques [4, 5] can estimate the frequency and amplitude of the spectral line directly from phase and modulus of the wavelet transform and no linear model is needed as in those of the discrete wavelet transform [6]. This paper will exploit such property of the continuous wavelet transform, the Morlet wavelet in particular, and focus on the problems such as a baseline, a solvent and non-Lorentzian lineshapes which commonly appear in NMR spectroscopy.

2. METHODOLOGY

In order to characterize a signal, the wavelet-based techniques first detect the frequencies in NMR signals and then estimate the amplitude at each detected frequency.

The wavelet transform of a signal $s(t)$ with respect to a

mother wavelet $g(t)$ is

$$S(\tau, a) = \frac{1}{2\pi} \sqrt{a} \int S(\omega) G^*(a\omega) e^{i\omega\tau} d\omega, \quad (1)$$

where $S(\omega)$ is the Fourier transform of the signal, a is a dilation parameter, τ is a translation parameter and $G^*(a\omega)$ is the complex conjugate of the Fourier transform of $g(t)$. Given a Lorentzian signal $s(t)$, namely

$$\begin{aligned} s(t) &= Ae^{-Dt} e^{i(\omega_s t + \phi)} \\ S(\omega) &= 2\pi A e^{i\phi} \delta(\omega - (\omega_s + Di)), \end{aligned} \quad (2)$$

where D and ϕ are the damping factor and the phase of the signal, the Morlet wavelet transform of $s(t)$ is

$$\begin{aligned} S(\tau, a) &= \sqrt{a} A e^{i\phi} e^{-D\tau} e^{i\omega_s \tau} G_M^*(a(\omega_s + Di)) \\ &= s(\tau) G_M^*(a(\omega_s + Di)), \end{aligned} \quad (3)$$

where

$$\begin{aligned} g_M(t) &= \frac{1}{2\pi\sigma} e^{-\frac{1}{2\sigma^2}t^2} e^{ik_0 t} \\ G_M(\omega) &= e^{-\frac{\sigma^2}{2}(\omega - k_0)^2}, \end{aligned} \quad (4)$$

is the Morlet wavelet whose frequency and width are denoted by k_0 and σ . It can be seen that the modulus of $S(\tau, a)$ is maximum, i.e. $\frac{\partial}{\partial a} S(\tau, a) \rightarrow 0$, when $\frac{\partial}{\partial a} G \rightarrow 0$. Given a condition that $a \in \Re$ and an assumption that $\omega_s \gg D$, the maximum can be found along the scale $a_r = k_0/\omega_s$ which then gives

$$G^*(a_r(\omega_s + Di)) = \exp\left(\left(\frac{\sigma a_r D}{\sqrt{2}}\right)^2\right), \quad (5)$$

and consequently

$$S_{a_r}(\tau) = \sqrt{a_r} \exp\left(\left(\frac{\sigma a_r D}{\sqrt{2}}\right)^2\right) s(\tau), \quad (6)$$

is also identical to the signal $s(t)$ scaled by a coefficient of a still-unknown D . Next, consider the phase of the Morlet wavelet transform along the ridge a_r ,

$$\begin{aligned} \angle S_{a_r}(\tau) &= \omega_s \tau + \phi \\ \omega_s &= \frac{\partial}{\partial \tau} \angle S_{a_r}(\tau). \end{aligned} \quad (7)$$

That is, the instantaneous frequency on the ridge a_r of the Morlet transform is ω_s . By Eq. (7), the phase ϕ can also be

Figure 1: (a) Phase of the wavelet transform of $g(t)$ with $\omega_s = 32$ and 64 rad/s and (b) its instantaneous frequencies. Note: $\sigma = 1$, $k_0 = 5$, $F_s = 256$, $l = 1024$.

recovered, if needed. This method is also applicable to an n -frequency signal if its frequencies are *sufficiently* far away from each other that $G^*(a\omega)$ can treat each spectral line independently [7] as illustrated in Fig. 1 when the instantaneous frequency of the wavelet transform converges to the two frequencies of a signal. Fig. 1 (b) also shows that Eq. (7) works not only on the ridge a_r but also for a wide range of a . On a condition that two frequencies are very close to each other (this also depends on the sampling frequency), increasing the frequency of the Morlet function k_0 can better localize and distinguish the overlapped frequencies.

Next, consider the modulus of the wavelet transform along a_r ,

$$|S_{a_r}(\tau)| = \sqrt{a_r} \exp\left(\left(\frac{\sigma a_r D}{\sqrt{2}}\right)^2\right) |s(\tau)|$$

$$\ln |S_{a_r}(\tau)| = \frac{1}{2} \ln a + \left(\frac{\sigma a_r D}{\sqrt{2}}\right)^2 + \ln A - D\tau.$$

That is,

$$D = -\frac{\partial}{\partial \tau} \ln |S_{a_r}(\tau)|. \quad (8)$$

Figure 2: Derived damping factor and amplitude of a signal with $D=1.5$, $A=2$, and $\omega_s = 32$ rad/s, at a_r . Same parameters as in Fig. 1.

Knowing D can now lead to the estimation of the amplitude resonance A of the signal, i.e.

$$A = |s(t)| e^{D\tau}. \quad (9)$$

The Morlet wavelet is the most frequently used in practical because of its simple numerical implementation and the vanishing of the third-order differentiation of its phase can also simplify the computation [5]. If the signal also includes a noise, [4] suggested averaging the instantaneous frequency on the ridge, i.e.

$$\bar{\Omega}_a = \frac{1}{T} \int_{\tau_0}^{\tau_0+T} \Omega_a(\tau) d\tau,$$

where $\Omega_a(\tau) = \frac{\partial}{\partial \tau} \angle S_{a_r}(\tau)$. Fig. 3 shows that the averaging gives a more stable $\bar{\Omega}$ as it creates a wider range of steady points along a . Note that Eq. (6) differs from the literature which approximates the wavelet transform by the Taylor series and omits the term D .

2.1 Apodization

In general, using the Fourier transform to analyze a signal can have erroneous results due to discrete implementation, e.g. aliasing, picket-fence effect, etc. Basically, this means that the sampling frequency (F_s) and the length of the signal (l) need to be carefully selected. The problem becomes more severe when two frequencies are close together. To solve this, the frequency resolution can be increased by zero padding the signal. However, it may introduce the ringing effect which is another consequence of a finite data set. Techniques such as decay padding, data-tapering window or wrap-around can be applied to reduce this boundary effect [8]. In NMR spectroscopy, the Gaussian or Lorentzian window is commonly used and such windowing process is known as apodization. For the continuous wavelet transform, the boundary effect increases linearly with a , which can be seen as a cone in Fig. 1 (a) and Fig. 2. However, by using $\bar{\Omega}$ outside this cone, there is no need to apply a tapering window to the signal.

Figure 3: The instantaneous frequency of a signal of 32 rad/s with SNR=10 (additive complex Gaussian noise with $\sigma_n = 0.079$) derived by the Morlet wavelet at $t = 4.7$ s. Note: $\sigma=1$, $k_0=5$, $F_s=800$, $l=1024$.

2.2 Baseline

A baseline corresponds to underlying broad resonances of large molecules, known as macromolecules, and lipids. It can affect the characterization of an NMR signal when the Fourier transform is used. Here, the baseline is modelled by cubic splines to study the performance of the wavelet transform. Fig. 4 shows that the baseline has no effect with the derived frequency or amplitude. In fact, Fig. 5 tells us that the baseline has its effect only at the edge of the transform. Although the spline is used to simplify the problem, if the real baseline satisfies an assumption that it converges much faster than the actual signals, using the wavelet transform to derive the frequency and amplitude of an NMR signal should still work without removing the baseline beforehand.

2.3 Solvent

The Morlet wavelet transform sees the signal at each frequency individually, therefore it can work well even if the amplitude at each frequency is hugely different, which normally occurs when there is a peak of solvent in the signal. As an example, the Morlet wavelet transform has been applied to a signal

$$s(t) = 100e^{-8.5t}e^{i32t} + e^{-1.5t}e^{i60t} + e^{-0.5t}e^{i90t} + e^{-t}e^{i120t} + e^{-2t}e^{i150t},$$

as seen in Fig. 6. It is a signal with an amplitude of 100 at 32 rad/s and 1 elsewhere. The high amplitude can affect other frequencies if they are close to each other. Using the aforementioned method, the amplitude of 1 can be extracted as 0.98, 0.91, 0.99 and 0.97 respectively. The error ranges within 1.2-8.9%, without any preprocessing.

3. NON-LORENTZIAN LINESHAPE

The Lorentzian lineshape assumes that the homogeneous lifetime broadening and pure dephasing are equally contributed from each individual molecule. However, molecules have different relaxation rates in general. In addition, there

(a)

(b)

Figure 4: (a) The Fourier transform of a 32-rad/s signal with baseline and its instantaneous frequency in (b). Parameters used are the same as in Fig. 1. The baseline is modelled by a cubic spline.

Figure 5: The magnitude of the wavelet transform of a pure 32-rad/s signal (left) and the signal with baseline (right).

are other sources, such as inhomogeneous distribution of the molecules, Doppler shift or site differences of molecules in the solution, that can cause the inhomogeneous broadening. These effects are typically modelled by a Gaussian lineshape [9]. Since the inhomogeneous broadening is often significantly larger than the lifetime broadening, the Gaussian lineshape is often dominant.

Figure 6: The Fourier transform of a signal with different amplitudes and the extracted spectrum by the Morlet wavelet.

3.1 Gaussian and Voigt lineshapes

Let us define a pure Gaussian function with a frequency at ω_s as

$$s_G(t) = Ae^{-\gamma t^2} e^{i\omega_s t}, \quad (10)$$

where γ is a Gaussian damping factor. By solving the Gaussian integral, its Morlet wavelet transform at the scale $a_r = k_0/\omega_s$ is then

$$S_{G,a_r}(\tau) = k_1 A e^{-k_2 \tau^2} e^{i\omega_s \tau}, \quad (11)$$

where

$$k_1 = \sqrt{\frac{a_r}{2\pi(2\gamma\sigma^2 a_r^2 + 1)}} \\ k_2 = \frac{\gamma}{2\gamma\sigma^2 a_r^2 + 1},$$

which is also a Gaussian function at the frequency ω_s . This new Gaussian function has its instantaneous frequency equal to ω_s . Therefore, similar to the process of the Lorentzian lineshape, A and γ can be achieved as follows:

1. Find $\omega_s = \frac{\partial}{\partial \tau} \angle S_{G,a_r}(\tau)$.
2. Find γ from $\frac{\partial^2}{\partial \tau^2} \ln |S_{G,a_r}(\tau)|$.
3. Find A from the calculated ω_s and γ .

Note that the scale $a_r = k_0/\omega_s$ does not give exactly the maximum modulus of the wavelet transform but it is acceptable on a condition that $a \in \Re$ and $\omega_s \gg D$.

On the other hand, if the lineshape is intermediate between a Gaussian and a Lorentzian form, the spectrum can be fitted to a convolution of the two functions. Such lineshape is known as a Voigt profile. It can be used to resolve the lineshape into homogeneous (Lorentzian) and inhomogeneous (Gaussian) components. The Morlet wavelet transform at the scale $a_r = k_0/\omega_s$ of a Voigt lineshape

$$s_V(t) = Ae^{-\gamma t^2} e^{-Dt} e^{i\omega_s t}, \quad (12)$$

is

$$S_{V,a_r}(\tau) = k_3 A e^{-k_2(\tau+k_4)^2} e^{i\omega_s \tau}, \quad (13)$$

where

$$k_3 = k_1 e^{-\frac{D^2}{4\gamma}} \\ k_4 = \frac{D}{2\gamma}$$

That is, at the scale a_r , the Morlet wavelet transform of the Voigt lineshape is also a Gaussian function with the same width as that of the Gaussian lineshape but shifted in time and amplitude modified. Its instantaneous frequency is also equal to ω_s along the ridge a_r , as shown in Fig. 7 (a). In addition, the second derivative of the modulus of the wavelet transform can be used to describe the second-order broadening of the lineshape, i.e. γ , either it is Gaussian or Voigt by

$$\gamma = -\frac{0.5}{\left(\frac{\partial^2}{\partial \tau^2} \ln |S_{G,a_r}(\tau)|\right)^{-1} + \sigma^2 a_r^2}. \quad (14)$$

This is confirmed by the convergence to the same value for both lineshapes in Fig. 8 (a).

3.2 Kubo's lineshape

The interaction between homogeneous and inhomogeneous broadening of the lineshape depends on the time scale. For example, if the relaxation time (T_2) is much longer than any effects modulating the energy of a molecule, the lineshape will approach the homogeneous lineshape. On the contrary, if T_2 is short, the lineshape is likely to be Gaussian. In [10], a so-called Gaussian-Markovian modulation, namely

$$s_K(t) = Ae^{-\frac{\zeta}{\gamma^2}(e^{-\gamma t} - 1 + \gamma t)} e^{i\omega_s t}, \quad (15)$$

is used to account for this time scale. The parameter γ is inversely proportional to T_2 and ζ is the amplitude of the solvent-induced fluctuations in the frequency. If $\alpha = \gamma/\zeta \ll 1$, the lineshape becomes Gaussian whereas $\alpha \gg 1$ leads to Lorentzian. Solving Eq. (15) seems to be complicated, though may be possible. However, the Morlet's instantaneous frequency at the scale $a_r = k_0/\omega_s$ is still capable of deriving the ω_s , even better than the Gaussian lineshape, as shown in Fig. 7 (a). The damping parameters can also be derived by a linear relation with $\frac{\partial}{\partial \tau} \ln |S_{G,a_r}(\tau)|$, as seen in Fig. 8 (b), whereas α relates directly to $\frac{\partial^2}{\partial \tau^2} \ln |S_{G,a_r}(\tau)|$.

4. CONCLUSION

This paper presents an analytical analysis of the Morlet wavelet transform to quantify NMR signals. The wavelet works well with Lorentzian, Gaussian, Voigt and Kubo lineshapes. It is also efficient when baseline, noise or solvent presented in the signals. Now, the method is under developed for use in *in vivo* signals acquired by our partners at UCBL (Lyon) and EPFL (Laussane).
