27 **Abstract**

28  
29 Balancing of intermittent energy such as solar energy can be achieved by bat-  
30 teries and hydrogen-based storage. However, combining these systems received  
31 limited attention in a grid-connected framework and its design optimization  
32 is often performed assuming fixed parameters. Hence, such optimization in-  
33 duces designs highly sensitive to real-world uncertainties, resulting in a dras-  
34 tic mismatch between simulated and actual performances. To fill the research  
35 gap on design optimization of grid-connected, hydrogen-based renewable energy  
36 systems, we performed a computationally efficient robust design optimization  
37 under different scenarios and compared the stochastic performance based on  
38 the corresponding cumulative density functions. This paper provides the opti-  
39 mized stochastic designs and the advantage of each design based on the financial  
40 flexibility of the system owner. The results illustrate that the economically pre-  
41 ferred solution is a photovoltaic array when the self-sufficiency ratio is irrelevant  
42 ( $\leq 30\%$ ). When a higher self-sufficiency ratio threshold is of interest, i.e. up to  
43 59%, photovoltaic-battery designs and photovoltaic-battery-hydrogen designs

## 21 **1. Introduction**

22  
23  
24  
25 With an expected increase of 575 GW between 2018 and 2023, solar Pho-  
26  
27 toVoltaic (PV) systems dominate the renewable capacity growth [1]. Despite  
28  
29 this expected capacity expansion, PV systems are unable to cover the entire  
30  
31 electricity demand, due to the intermittent behavior of solar energy. To address  
32  
33 this intermittency, the addition of an electrical energy storage system enables to  
34  
35 store an excess of solar energy and to reproduce this energy when electricity de-  
36  
37 mand exceeds PV production. For such intermittent balancing, battery energy  
38  
39 storage and hydrogen energy storage provide a flexible, adequate solution [2].  
40  
41 Battery storage achieves a fast response time and a high round-trip efficiency  
42  
43 ( $\approx 80\%$ , as opposed to  $\approx 35\%$  for hydrogen storage), which makes it suitable for  
44  
45 short-term energy storage (i.e. from seconds to days) [2]. Nevertheless, due to  
46  
47 their self-discharge rate and low energy density (30 Wh /kg), batteries are sub-  
48  
49 optimal for long-term energy storage (i.e. from weeks to months) [3]. Instead,  
50  
51 hydrogen storage is suggested for seasonal energy storage, as hydrogen storage  
52  
53 operates with a negligible discharge rate, achieves a higher energy density (up  
54  
55 to 10 kWh /kg) and provides a flexible capacity setting of power charging, en-  
56  
57 ergy storage and power discharging [2, 3]. In this framework, power charging is  
58  
59 generally performed by splitting water into hydrogen and oxygen in a Proton  
60  
61 Exchange Membrane (PEM) electrolyzer [4], because of its fast response time  
62  
63 ( $< 1$  s) and full load flexibility [5]. The reverse reaction is generally performed  
64  
65 in a PEM fuel cell to discharge the power [6]. The PEM fuel cell technology

23 is widespread commercially, it operates at low temperature (70 °C- 100 °C) and  
10 achieves high power densities (up to 2 W/cm<sup>2</sup>) [7].  
11

12  
13 Design optimization studies on standalone Hybrid Renewable Energy Sys-  
14 tems (HRES) including battery storage and hydrogen storage are well-established [8].

15  
16 Han et al. described a mode-triggered droop scheme for an islanded PV-battery-  
17 hydrogen DC microgrid and showed that combining hydrogen storage and bat-  
18 tery storage provides stronger environmental adaptability and higher PV uti-  
19 lization [9]. Khiareddine et al. performed a design optimization of a stand-alone  
20 PV-wind-battery-hydrogen system and concluded that an adequately sized fuel  
21 cell array allows a significant reduction in battery capacity and thus reduction  
22 of the total cost [10]. Zhang et al. evaluated different configurations of a stand-  
23 alone PV-wind-battery-hydrogen system and concluded that battery storage is  
24 the most cost-effective solution, while hydrogen storage is a reliable and non-  
25 polluting alternative, which can become economically advantageous after cost  
26 and efficiency improvements [11]. Recently, also design optimization studies on  
27 grid-connected Hybrid Renewable Energy Systems (HRES) including battery  
28 storage and hydrogen storage received attention. Parra et al. illustrated the in-  
29 crease in on-site energy production of a PV-powered, grid-connected dwelling by  
30 considering battery and hydrogen storage, resulting in an additional annual in-  
31 come of £112 and £102, respectively [12]. Pellow et al. compared battery storage  
32 and hydrogen storage for grid-connected systems and conclude that hydrogen  
33 storage achieves a higher electrical Energy Stored On Invested than battery stor-  
34 age [13]. Zhang et al. optimized a grid-connected PV-battery-hydrogen system,  
35 considering several operation strategies and two different cost scenarios [3]. Un-  
36 der the optimistic cost scenario, hydrogen storage induces a higher Net Present  
37 Value. Despite the clear advantage of this type of HRES, Eriksson et al. high-  
38 lighted that incorporating hydrogen in HRES design optimization is still an  
39 anomaly: only 5 out of 30 surveyed HRES studies incorporated hydrogen-based  
40 energy systems [14].

However, the HRES performance is mainly characterized by parameters subject to uncertainty (e.g. stochastic nature of solar energy, operation and maintenance costs, operating temperature) [15]. Moreover, in the hydrogen market, it remains a big challenge to obtain real market values [16]. Consequently, the uncertainty on these parameters affects the HRES performance, leading to a stochastic behavior of the system objectives. The state-of-the-art method that propagates parameter uncertainties through a system model and quantifies the statistical moments of the model output (i.e. Uncertainty Quantification (UQ)) is Monte Carlo Simulation [17]. This method is a robust (i.e. always converging) and easy-to-implement technique, but it requires a significant number of model evaluations ( $10^4 - 10^5$ ) to attain an acceptable level of convergence on the statistical moments. Computationally-efficient alternatives are surrogate model construction methods, such as Gaussian Process Regression [18] and Polynomial Chaos Expansion (PCE) [19]. During the post-process of the surrogate model (i.e. quantification of the statistical moments), PCE provides significant advantages, such as the analytic quantification of the statistical moments and the Sobol' indices out of the PCE coefficients [20].

When the mean and standard deviation of a model output can be quantified efficiently, these statistical moments can be used as optimization objectives. Through a multi-objective optimization algorithm, a Pareto set of optimized designs can be found that makes a trade-off between minimizing the output mean and minimizing the output standard deviation (i.e. Robust Design Optimization (RDO)). The design leading to the minimum standard deviation on the model output (i.e. the robust design) is least-sensitive to the parameter uncertainties and therefore provides the most resilient performance. In the framework of RDO, the Taguchi methodology quantifies the mean square deviation of several designs subject to noise [21]. A gradual setting of worst-case scenario-based design optimization aims to minimize the loss in objective function by considering least favorable conditions (i.e. min-max optimization) [22]. In surrogate-assisted RDO, the output mean and output standard deviation for every design sample are quantified via a surrogate modelling method [23].

85 In design optimization studies of HRES, the optimal integration of battery  
86 systems and hydrogen-based energy systems in grid-connected applications re-  
87 ceived limited attention. Moreover, the model parameters are often assumed  
88 fixed and free from inherent variations, while the rare consideration of uncer-  
89 tainty is limited to linear models and only a handful of uncertain parameters  
90 ( $< 5$ ), characterized by generic ranges based on assumptions [24]. Akbari et al.  
91 evaluated a distributed energy system, subject to a general variability of  $\pm 20\%$   
92 for a handful of financial parameters and demand parameters [25]. Parisio et al.  
93 considered the converter efficiencies related to electricity and heat demand to  
94 be uncertain between a general range of  $\pm 10\%$  on a linear model of an energy  
95 hub [26]. These linear models are subject to large inherent uncertainty, while the  
96 variation of other highly-uncertain parameters (e.g. investment cost, lifetime)  
97 during real-world design, planning and operation is ignored. Moreover, generic  
98 variability ranges assume equal weights for every uncertainty, which leads to bi-  
99 ased results. Combined, these assumptions bring forward designs that are highly  
100 sensitive to real-world uncertainties and result in a drastic mismatch between  
101 simulated and actual performances. To fill the research gap on design optimiza-  
102 tion under uncertainty of grid-connected, HRES including hydrogen storage and  
103 battery storage, we provide the following main contributions: the significant  
104 techno-economic uncertain parameters are characterized by their uncertainty as  
105 described in literature; to handle this large stochastic dimension, the advantages  
106 of the sparse PCE algorithm developed by Abraham et al. are exploited for the  
107 first time in a surrogate-assisted RDO algorithm [27]; the Cumulative Density  
108 Functions (CDF) of the optimized designs are used to compare the respective  
109 stochastic performances, which provides new insights into the probability of at-  
110 taining an affordable leveled cost of electricity when combining battery storage  
111 and hydrogen storage with a PV array.

112 In this paper, the HRES model and the RDO method are described in sec-  
113 tion 2. The optimized designs for every demand type and their stochastic per-  
114 formance are presented in section 3. Conclusively, section 4 illustrates the main  
115 conclusions of this work, while the appendix consists of the detailed dataset and

116 convergence curves of the sparse PCE method.

117 **2. Method**

118 This section introduces the HRES, followed by the Python-based component  
119 models and the quantities of interest. Thereafter, the uncertainty characteri-  
120 zation is described and the method to propagate the uncertainties through the  
121 model is presented. Finally, the RDO algorithm is illustrated.

122 *2.1. Hybrid Renewable Energy System model*

123 The considered system is a grid-connected load, supported by an HRES (Fig-  
124 ure 1). The HRES consists of a PV array, which is coupled to a DC bus bar  
125 through a DC-DC converter with Maximum Power Point Tracking. A battery  
126 stack and electrolyzer array with storage tank are integrated to store the excess  
127 of PV array electricity. A fuel cell array is implemented to produce electric-  
128 ity from the stored hydrogen. To transfer the DC electricity from the battery  
129 system and fuel cell to the AC load, a DC-AC converter is connected.

130 To set the hierarchy between the subsystems, a typical power management  
131 strategy is implemented, which primarily aims to satisfy the demand [28]. In  
132 this strategy, excess PV power is supplied to the battery stack. When the  
133 determined charge current violates the maximum charge current, the nominal  
134 charge current is considered instead. Then, or when the battery array reaches  
135 its maximum State Of Charge (SOC), the surplus energy is used to power the  
136 electrolyzer array. When the hydrogen tank is full, or when the surplus power  
137 lies outside the electrolyzer array operating range, the surplus energy is sold to  
138 the grid at the wholesale electricity price.

139 In the opposite case, when the PV array does not cover the demand, the  
140 remaining demand is covered by the battery array, if the discharge current does  
141 not violate the maximum discharge current and the SOC remains above the SOC  
142 lower limit. If not, nominal discharge current is extracted and the additional  
143 power is supplied by the fuel cell array. When insufficient, the grid covers the  
144 remaining demand.

Figure 1: The considered system includes the load connected to the grid and supported by a Hybrid Renewable Energy System (HRES). This HRES consists of a PhotoVoltaic (PV) array which converts solar energy into electricity. The battery stack and hydrogen-based energy system (electrolyzer, fuel cell and storage tank) enable the system to store an excess of PV array electricity and to comply, up to the available energy, with the demand when the solar irradiance is insufficient.

### 2.1.1. Photovoltaic array

To determine the electricity produced by a PV array, we imported the experimentally-validated model out of the PVlib Python library [29]. The model quantifies the PV panel current-voltage characteristic through the following single-diode equation:

$$I_{PV} = I_L - I_0 \left( \exp \left( \frac{U + IR_s}{n_{diode} N_s U_{th}} \right) - 1 \right) - \frac{U + IR_s}{R_{sh}}. \quad (1)$$

1  
2  
3  
4  
5  
6  
7  
8  
9  
10 The parameters in Equation 1 are not provided by the PV manufacturer. There-  
11 fore, we adopted the method by De Soto et al. to determine these parameters  
12 out of manufacturer data [30].  
13

### 14 2.1.2. Battery stack

15  
16 Lead-acid battery technology is selected in this work, as it is the most  
17 widespread technology and a mature lead-acid battery industry exists with sig-  
18 nificant learning rates during the last decades [31]. To characterize the per-  
19 formance of a lead-acid battery stack, we adopted the experimentally-validated  
20 model of Blaifi et al. [32]. The general voltage-current relation for a lead-acid  
21 battery is defined as:  
22  
23  
24  
25

$$26 U_{\text{bat}} = U_{\text{bat,oc}} + I_{\text{bat}} R_{\text{bat}}, \quad (2)$$

27  
28 where the current  $I_{\text{bat}}$  is positive during charge and negative during discharge.  
29 The resistance component  $R_{\text{bat}}$  is different during charge and discharge and  
30 depends on the temperature, the current magnitude and the capacity. Hence,  
31 the characterization of the voltage during charge and discharge is given by:  
32  
33  
34  
35

$$36 U_{\text{ch}} = (2.085 - 0.12 (1 - \text{SOC})) - \frac{I}{C_{\text{nom}}} \left( \frac{4}{1 + I^{1.3}} + \frac{0.27}{\text{SOC}^{1.5}} + 0.02 \right) (1 - 0.007\Delta T), \quad (3)$$

$$37 U_{\text{dch}} = (2 - 0.16 \text{SOC}) + \frac{I}{C_{\text{nom}}} \left( \frac{6}{1 + I^{0.86}} + \frac{0.48}{(1 - \text{SOC})^{1.2}} + 0.036 \right) (1 - 0.025\Delta T). \quad (4)$$

38  
39  
40  
41  
42  
43  
44  
45  
46 The State Of Charge (SOC) is the fraction of the total capacity stored in the  
47 battery:  
48  
49

$$50 \text{SOC}(t) = \text{SOC}_0 + \frac{1}{C(t)} \int_0^t \eta_{\text{bat}}(t) I(t) dt, \quad (5)$$

51  
52 In this work, the minimum SOC is set at 20 % [33, 34].

53  
54 We estimated the lifetime based on SOC variations through the commonly  
55 implemented Rainflow cycles counting method [35]. To avoid excessive reduction

169 of the lifetime, overcharging and over discharging are avoided, while the max-  
170 imum charge current and maximum discharge current are limited to  $C_{\text{nom}}/10$   
171 and  $C_{\text{nom}}/3.3$ , respectively [36]. Because of the constraints limiting the opera-  
172 tion in the optimal operating zone to prolong battery life, we assumed a yearly  
173 capacity degradation rate [37] and a fixed energy efficiency of 80 % [38].

### 174 2.1.3. Electrolyzer array

175 To determine the voltage-current characteristic and hydrogen flow rate of  
176 the PEM electrolyzer array, we selected the experimentally-validated model from  
177 Abdin et al. and we consider an operating pressure of 30 bar [39]. The operating  
178 voltage is characterized according to the following equation:

$$U_{\text{elec}} = U_{\text{elec,oc}} - U_{\text{elec,act}} - U_{\text{elec,ohm}} - U_{\text{elec,con}}. \quad (6)$$

179 In the remainder of this subsection, the subscript "elec", which refers to "elec-  
180 trolyzer", is left out for ease of reading. The open-circuit voltage follows out of  
181 the Nernst equation for electrolysis:

$$U_{\text{oc}} = (1.229 - 0.9 \times 10^{-3} (T - 298)) + \frac{R_{\text{u}}T}{2F} \left( \ln \left( \frac{p_{\text{H}_2} \sqrt{p_{\text{O}_2}}}{a_{\text{H}_2\text{O}}} \right) \right), \quad (7)$$

182 where  $R_{\text{u}}$ ,  $F$  and  $a$  represent the universal gas constant, Faraday constant and  
183 water activity between electrode and membrane, respectively. The activation  
184 overpotential  $U_{\text{act}}$  represents the voltage used to transfer electrons between the  
185 electrodes. By inverting the Butler-Volmer equation for the reactions at the  
186 electrode surface, the activation voltage can be quantified:

$$U_{\text{act}} = \frac{R_{\text{u}}T}{\alpha_{\text{an}}F} \operatorname{arcsinh} \left( \frac{i}{2i_{0,\text{an}}} \right) + \frac{R_{\text{u}}T}{\alpha_{\text{cat}}F} \operatorname{arcsinh} \left( \frac{i}{2i_{0,\text{cat}}} \right). \quad (8)$$

187 At high currents, a concentration overpotential  $U_{\text{con}}$  is created due to an excess  
188 of reactants (e.g. oxygen bubbles slowing down the reaction). To quantify this  
189 overpotential, a combination of the Nernst equation and Fick's law is adopted:

$$U_{\text{con}} = \frac{R_{\text{u}}T}{4F} \ln \frac{C_{\text{O}_2}^{\text{mem}}}{C_{\text{O}_2,0}^{\text{mem}}} + \frac{R_{\text{u}}T}{2F} \ln \frac{C_{\text{H}_2}^{\text{mem}}}{C_{\text{H}_2,0}^{\text{mem}}}, \quad (9)$$

1  
2  
3  
4  
5  
6  
7  
8  
9 where  $C^{\text{mem}}$  is the concentration at the membrane-electrode interface, and the  
10 subscript 0 refers to the reference working condition. The final overpotential  
11 that occurs in the PEM electrolyzer is the ohmic overpotential  $U_{\text{ohm}}$ , which is  
12 driven by the electric resistance of the electrodes  $R_{\text{el}}$ , bipolar plates  $R_{\text{pl}}$  and the  
13 membrane  $R_{\text{mem}}$ :  
14  
15  
16

$$U_{\text{ohm}} = I(R_{\text{el}} + R_{\text{pl}} + R_{\text{mem}}). \quad (10)$$

17  
18  
19  
20 The electric resistance of the electrodes and the flow plates can be quantified  
21 by applying Ohms law. We refer to Abdin et al. for further details on the  
22 determination of the overpotentials [39]. Finally, following the working point of  
23 the electrolyzer array, the hydrogen molar flow rate  $n_{\text{H}_2}$  is formulated as:  
24  
25  
26

$$n_{\text{H}_2} = \frac{I}{2F}. \quad (11)$$

27  
28  
29  
30 Despite the effect of intermittent loading on degradation and lifetime is not  
31 yet well quantified, this effect is reported to be negligible by several manufac-  
32 turers [5]. Therefore, this effect is not considered in this study and a fixed  
33 degradation rate per operating hour is assumed.  
34  
35  
36

#### 37 38 2.1.4. Hydrogen storage tank

39 The pressurized hydrogen produced in the electrolyzer is stored in a stor-  
40 age tank. Filling up the storage tank increases the tank pressure, until the  
41 electrolyzer outlet pressure is reached, according to the ideal gas law [40]:  
42  
43  
44

$$p_{\text{t}} - p_{\text{t,init}} = Z \frac{N_{\text{H}_2} R_{\text{u}} T_{\text{t}}}{M_{\text{H}_2} V_{\text{t}}}. \quad (12)$$

45  
46  
47  
48 The compressibility factor  $Z$  for  $\text{H}_2$  is equal to 1 at room temperature and  
49 moderate pressure ( $< 100$  bar) [40].  
50  
51

#### 52 53 2.1.5. Fuel cell array

54 To represent the conversion of hydrogen and oxygen into water in a PEM fuel  
55 cell array, we adopted the model from Murugesan et al. which is experimentally  
56  
57  
58

1  
2  
3  
4  
5  
6  
7  
8  
9  
212 validated on the Ballard-Mark-V PEM fuel cell [41]. The operating current  
213 depends on the converted hydrogen molar flow rate:

$$I_{\text{FC}} = 2Fn_{\text{FC,H}_2}. \quad (13)$$

214 The electric potential produced during water composition out of hydrogen and  
215 oxygen is equal to the Nernst potential minus the losses:

$$U_{\text{FC}} = U_{\text{FC,Nernst}} - U_{\text{FC,act}} - U_{\text{FC,ohm}} - U_{\text{FC,con}}. \quad (14)$$

216 In the remainder of this subsection, the subscript "FC" is left out for ease of  
217 reading. The Nernst equation determines the maximum fuel cell voltage and  
218 considers the operating temperature and reactant pressures:

$$U_{\text{Nernst}} = 1.229 - 0.85 \times 10^{-3}(T - 298.15) + 4.31 \times 10^{-5}T (\ln(p_{\text{H}_2}) + 0.5 \ln(p_{\text{O}_2})). \quad (15)$$

219 The activation losses  $U_{\text{act}}$  occur due to a low rate of charge transfer at lower  
220 current densities. This activation loss corresponds to:

$$U_{\text{act}} = -0.948 + 0.00354T + 7.6 \times 10^{-5}T \ln(C_{\text{O}_2}) + -1.93 \times 10^{-4}T \ln(I). \quad (16)$$

221 The ohmic losses  $U_{\text{ohm}}$  occur out of electrolyte resistance, contact resistance at  
222 the collector plates and at the graphite electrodes. This loss is linearly depen-  
223 dent to the load:

$$U_{\text{ohm}} = iR_{\text{ohm}} = i \frac{\delta_{\text{mem}}}{\sigma_{\text{mem}}}, \quad (17)$$

224 where  $R_{\text{ohm}}$  is the electrical resistance that depends on the membrane thickness  
225  $\delta_{\text{mem}}$  and membrane conductivity  $\sigma_{\text{mem}}$  (Nafion 117). The concentration loss  
226 occurs due to changes in concentration of reactants at higher current density  
227 region:

$$U_{\text{con}} = -0.016 \ln \left( 1 - \frac{i}{i_{\text{lim}}} \right). \quad (18)$$

228 We refer to the work of Murugesan et al. for the detailed quantification of these  
229 losses [41]. Similar to the PEM electrolyzer, the effect of intermittent operation  
230 on the degradation and lifetime is not yet fully understood [42]. Therefore, a  
231 fixed degradation rate per operating hour is assumed.

232 *2.1.6. Power conversion*

233 The components are connected to a DC bus bar through DC-DC converters.  
234 To provide the power to the load or the grid, the DC bus bar is connected  
235 through a DC-AC inverter. The conversion efficiency of a DC-DC converter  
236  $\eta_{\text{conv}}$  depends on the component output power:

$$P_{\text{DC,out}} = \eta_{\text{conv}}(P_{\text{DC,out}}) P_{\text{DC,in}}. \tag{19}$$

237 The conversion efficiency depends on the converter type. We considered the ex-  
238 perimentally buck-boost converter efficiency profile presented by Taghvaei et al.  
239 for the PV array, PEM electrolyzer array and fuel cell array and a bidirectional  
240 buck-boost converter efficiency profile for the battery stack [43]. Similar to the  
241 DC-DC converter, the DC-AC inverter efficiency profile  $\eta_{\text{inv}}$  depends on the AC  
242 output power  $P_{\text{AC,out}}$ :

$$P_{\text{AC,out}} = \eta_{\text{inv}}(P_{\text{AC,out}}) P_{\text{DC,in}}. \tag{20}$$

243 In this work, the inverter efficiency profile is determined by the experimentally-  
244 validated method described by Rampinelli et al. [44].

245 *2.2. Climate and demand data*

246 The HRES performance depends on the climate and demand characteristics.  
247 In this work, we evaluated a dwelling and a community (i.e. 2500 dwellings) in  
248 Brussels, Belgium (Figure 2). When adopting climate data and demand data,  
249 it is important to adopt the climate data that was used to generate the demand  
250 data, as the solar irradiance and ambient temperature affect how the demand  
251 behaves. Therefore, we appeal to Typical Meteorological Year data and hourly  
252 demand data from the National Renewable Energy Laboratory, as the former is

253 used to construct the latter [45, 46]. As the data only exists for locations in the  
254 United States of America, we applied the method presented by Montero Car-  
255 rero et al. to adapt the climate and demand profiles for Belgium [47].

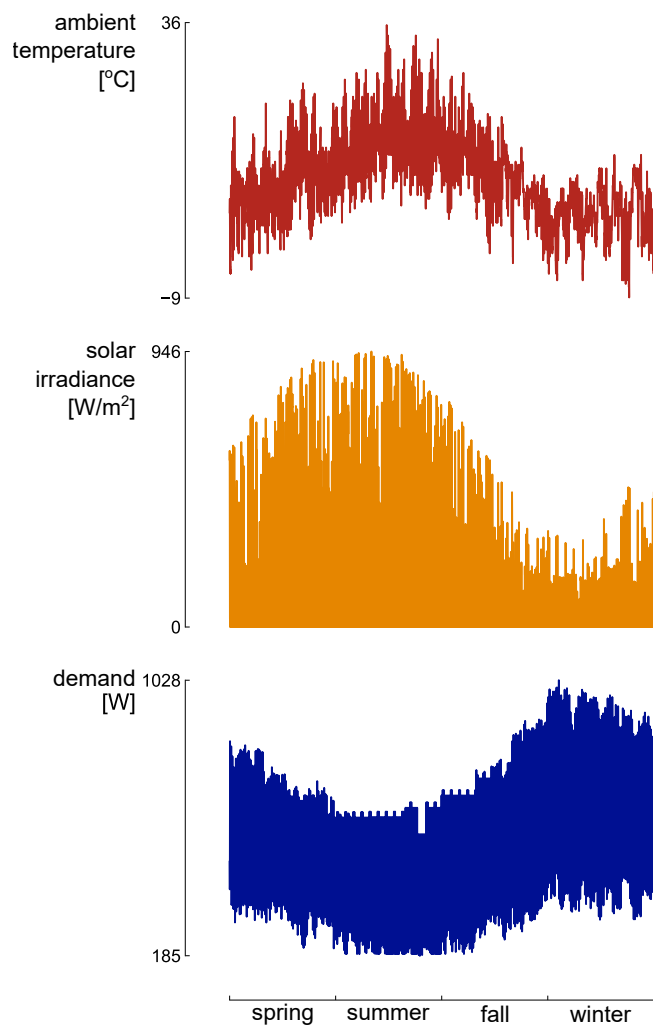

Figure 2: The climate data (solar irradiance and ambient temperature) and demand data are inversely proportional, resulting in a reduced demand during spring and summer and a peak demand during fall and winter.

3  
4  
5  
6  
7  
8  
9  
256 *2.3. Performance indicators*

257 To evaluate the techno-economic performance of the HRES, the Levelized  
258 Cost Of Electricity (LCOE) is selected. The LCOE of the hybrid system reflects  
259 the system cost per unit of electricity covered [33]:

$$\text{LCOE} = \frac{\text{CAPEX}_a + \text{OPEX}_a + R_{c,a} + G_{c,a} - G_{s,a}}{\sum_{i=0}^{8760} P_{\text{load}}}. \quad (21)$$

260 To determine the system cost, the annualized investment cost  $\text{CAPEX}_a$ , opera-  
261 tional cost  $\text{OPEX}_a$ , replacement cost  $R_{c,a}$ , grid electricity cost  $G_{c,a}$  and the gain  
262 from selling excess electricity  $G_{s,a}$  are evaluated. We refer to Zakeri et al. for the  
263 detailed quantification of these parameters [33]. The specific cost parameters  
264 values are listed in Table A.3.

265 To indicate the fraction of the load that is covered by the HRES, the Self-  
266 Sufficiency Ratio (SSR) is quantified as a secondary performance indicator [3]:

$$\text{SSR} = 1 - \frac{E_{\text{grid}}}{E_{\text{load}}}, \quad (22)$$

267 where  $E_{\text{load}}$  is the total energy demand over the system lifetime. The SSR is  
268 an important factor for adopters of HRES, as it illustrates the resilience against  
269 large electricity price increases and the protection against power cuts, which are  
270 more likely in the future [48]. Moreover, reaching a significant SSR threshold  
271 is beneficial for grid operators, as it reduces the simultaneous power extraction  
272 from the grid and therefore reduces the risk of black-outs.

273 *2.4. Uncertainty characterization*

274 To represent the uncertainty during design and operation of the HRES, the  
275 model parameters are characterized by a uniform distribution based on litera-  
276 ture (Table A.3). During operation, the system is subject to natural variability  
277 of the technical parameters, e.g. fluctuating operating temperature and pressure,  
278 varying degradation speed and an uncertain component lifetime. Additionally,  
279 inter-annual variability is present on the electricity demand, solar irradiance  
280 and ambient temperature [15]. From an economic point of view, the system is

1  
 2  
 3  
 4  
 5  
 6  
 7  
 8  
 9 281 subject to commissioning and maintenance quality, which affects the operating  
 10 282 and maintenance cost, uncertain replacement cost due to evolving market condi-  
 11 283 tions and a highly-uncertain wholesale electricity price due to an evolving energy  
 12 284 mix, improved energy efficiency and increased electrification of fossil-based en-  
 13 285 ergy sectors [49]. Otherwise, the interest rate and the investment cost can be  
 14 286 considered deterministic or uncertain, depending on the actual step of the design  
 15 287 process and the finance type considered [15]. Most studies assume a single-stage  
 16 288 investment at the project start, which implies a deterministic characterization  
 17 289 of these parameters. However, a change in the finance type of the project and  
 18 290 a significant timeframe between the design stage and investment stage, which  
 19 291 increases the possibility for the market conditions to change between the stages,  
 20 292 implies uncertainty on the interest rate and investment costs. Therefore, in  
 21 293 this work, two scenarios are assumed. The first scenario considers the interest  
 22 294 rate and investment costs as deterministic (i.e. fixed market conditions), while  
 23 295 the second scenario treats these parameters as uncertain (i.e. varying market  
 24 296 conditions). As the results are significantly influenced by the design step and  
 25 297 investment type, the handling of two scenarios enables to compare with both  
 26 298 commonly adopted scenarios in scientific literature.

299 *2.5. Uncertainty Quantification*

300 Following the computational cost of the model evaluation ( $\approx 150$  s) and the  
 301 large number of uncertainties considered (36 in the variable market conditions  
 302 scenario and 28 in the fixed market conditions scenario), we considered a com-  
 303 putationally efficient sparse Polynomial Chaos Expansion (PCE) method to  
 304 propagate the uncertainty and quantify the statistical moments of the HRES  
 305 performance indicators [27]. The PCE representation of the system model con-  
 306 sists of a series of orthogonal polynomials  $\Psi_i$  with corresponding coefficients  
 307  $u_i$ :

$$\hat{M}(\boldsymbol{\xi}) = \sum_{i=0}^P u_i \Psi_i(\boldsymbol{\xi}) \approx M(\boldsymbol{\xi}), \quad (23)$$

1  
2  
3  
4  
5  
6  
7  
8  
9  
308 where  $\boldsymbol{\xi} = (\xi_1, \xi_2, \dots, \xi_d)$  represents a vector of independent random parameters,  
10  
11  $d$  is the stochastic dimension and  $P + 1$  equals the number of terms in the  
12  
13 truncated series, determined by the polynomials up to a certain degree  $p$  for the  
14  
15 considered stochastic dimension  $d$ :

$$16 \quad P + 1 = \frac{(p + d)!}{p!d!}. \quad (24)$$

17  
18  
19 The number of terms in the truncated series increases dramatically when  $d > 10$   
20  
21 (i.e. *curse-of-dimensionality*) [50]. Therefore, we adopted the sparse PCE algo-  
22  
23 rithm developed in our research group which includes only the most significant  
24  
25 coefficients (and corresponding polynomials) in the truncated series [27]. To  
26  
27 determine the significant coefficients a priori, the algorithm first creates an ini-  
28  
29 tial design of experiments  $\chi = [\boldsymbol{\xi}^1, \boldsymbol{\xi}^2, \dots, \boldsymbol{\xi}^n]$ , which are evaluated through the  
30  
31 system model. In the first forward step of the algorithm,  $P + 1$  one-predictor  
32  
33 surrogate models are created and assessed individually by fitting their response  
34  
35 with the output of the system model evaluations. Each one-predictor model  
36  
37 and the variance of the coefficient are determined through the Least-Square  
38  
39 Minimization method. The best performing one-predictor model (i.e. the most  
40  
41 significant coefficient and corresponding orthogonal polynomial) is stored in the  
42  
43 final regression model and the polynomial is removed from the pool of basis  
44  
45 functions. This process is repeated until the maximum number of iterations  
46  
47 is reached. Additional details on this sparse PCE method are described by  
48  
49 Abraham et al. [27].

50  
51 When the coefficients are quantified, the mean  $\mu$ , standard deviation  $\sigma$   
52  
53 and Sobol' indices follow analytically through post-processing of the coefficients  
54  
55 (i.e. no additional model evaluations required). The total-order Sobol' indices  
56  
57 ( $S_i^{T,PC}$ ) quantify the total impact of a stochastic input parameter on the per-  
58  
59 formance indicator, including all interactions:

$$60 \quad S_i^{T,PC} = \sum_{\alpha \in A_i^T} u_\alpha^2 / \sum_{i=1}^P u_i^2 \quad A_i^T = \{\alpha \in A | \alpha_i > 0\}, \quad (25)$$

61  
62  
63  
64  
65  
333 where  $A$  is the set of all the PCE coefficients and  $\alpha_i$  represents the coefficient

1  
2  
3  
4  
5  
6  
7  
8  
9 related to uncertain parameter  $i$ .

10 In this work, a polynomial order of 3 is required to approximate the real  
11 model behavior accurately ( $< 1\%$  error on the statistical moments, compared  
12 to a Monte Carlo Simulation result). The sparse PCE method achieves similar  
13 accuracy to the full PCE with only 29% of the required model evaluations  
14 (Figure A.9), leading to a significant increase in computational efficiency of the  
15 method.  
16  
17  
18  
19  
20

## 21 2.6. Surrogate-assisted Robust Design Optimization

22 The surrogate-assisted RDO aims at finding an optimized design (or set of  
23 optimized designs) which minimizes the LCOE mean and minimizes the LCOE  
24 standard deviation. The LCOE mean indicates the average expected LCOE  
25 over the system lifetime and should, therefore, be minimized to foresee a cost-  
26 competitive design. However, the LCOE standard deviation indicates the un-  
27 certainty on that expected mean LCOE. Reducing the LCOE standard devia-  
28 tion decreases the sensitivity to the uncertain environment, which increases the  
29 probability of operating near that LCOE mean in reality. To be able to find the  
30 designs that minimize these objectives, the capacity of the PV array, battery  
31 stack, PEM electrolyzer array, PEM fuel cell array and storage tank are selected  
32 as continuous design parameters. By considering the capacities as independent  
33 design parameters, the optimization algorithm can exclude any technology from  
34 the HRES. Due to the complexity and non-linearity of the HRES, the Non-  
35 dominated Sorting Genetic Algorithm (NSGA-II) is selected as an optimization  
36 algorithm [51, 52]. The algorithm creates and evaluates an initial population of  
37 design samples. As the mean and standard deviation of the LCOE are required  
38 to evaluate the population, the sparse PCE method is applied to the HRES  
39 model for each design sample. Once the statistical moments on the LCOE  
40 for the population are known, the next generation is created out of the initial  
41 population, based on the dominating subset of design samples. The algorithm  
42 continues until the maximum number of iterations is realized. In this work, the  
43 population size is fixed at 50 design samples, following a rule of thumb of 10  
44

### 13 366 **3. Results and discussion**

14  
15  
16 367 The UQ and RDO methods are applied to the HRES to determine the op-  
17 368 timized designs and to evaluate their performance under the variable market  
18 369 conditions scenario and fixed market conditions scenario. First, the Pareto set  
19 370 of optimized designs is presented, supplemented by a global sensitivity anal-  
20 371 ysis to capture the driving uncertainties. Additionally, the stochastic design  
21 372 performance of these optimized designs is compared based on the Cumulative  
22 373 Distribution Function (CDF).  
23

27

#### 28 374 *3.1. Robust Design Optimization and global sensitivity analysis*

29  
30 375 The RDO method is applied four times independently on the HRES: for  
31 376 the dwelling and community in the fixed market conditions scenario and the  
32 377 variable market conditions scenario. In both scenarios, a trade-off exists between  
33 378 minimizing the LCOE mean and minimizing the LCOE standard deviation for  
34 379 the dwelling (Figure 3) and for the community (Figure 4), which is illustrated  
35 380 by the Pareto set of optimized designs. For each optimized design, the total  
36 381 Sobol' indices of the LCOE and the statistical moments of the corresponding  
37 382 SSR are quantified.  
38  
39  
40  
41  
42

43 383 The minimum LCOE mean is achieved by a PV array (e.g. 2.7 kW<sub>p</sub> for the  
44 384 dwelling), which in the variable market conditions scenario induces a slightly  
45 385 larger LCOE standard deviation (e.g. 55.9 €/MWh for the dwelling) than in  
46 386 the fixed market conditions scenario (e.g. 55.1 €/MWh for the dwelling), due to  
47 387 the additional uncertainty present on the PV array investment cost and interest  
48 388 rate (Figure 3 and Figure 4). For this design, the uncertainty related to the grid  
49 389 electricity price (i.e. wholesale electricity price and proportion of the wholesale  
50 390 electricity price in the total charged cost per MWh consumed) dominates the  
51 391 LCOE standard deviation, due to the significant dependency on the grid to

392 comply with the electricity demand (SSR mean = 30%). To reduce the LCOE  
393 standard deviation, at the expense of a minimal increase in LCOE mean, the  
394 Pareto set of optimized designs implies to increase the PV array capacity, which  
395 consequently increases the SSR mean and therefore decreases the Sobol' indices  
396 related to grid electricity. To illustrate for the dwelling, increasing the PV array  
397 capacity proves to be a cost-efficient approach (i.e. with minimal increase in  
398 LCOE mean) to decrease the LCOE standard deviation down to 48.5€/MWh  
399 in the variable market conditions scenario and down to 42.6€/MWh in the  
400 fixed market conditions scenario. Despite the LCOE standard deviation can  
401 be reduced modestly by increasing the PV array capacity, the proposed PV  
402 designs remain primarily dependent on grid electricity (SSR mean < 40%) and  
403 the envisioned LCOE is therefore subject to a significant standard deviation.

404 To further decrease the LCOE standard deviation over a higher SSR mean  
405 threshold (e.g. SSR mean > 40% for the community, Figure 4), PV-battery de-  
406 signs are configured by the optimization algorithm, instead of further increasing  
407 solely the PV array capacity. This because the SSR mean stagnates over a  
408 certain PV capacity threshold, while the inclusion of a battery stack enables to  
409 cover part of the demand when insufficient solar irradiance is available. Hence,  
410 the optimization algorithm suggests designs which subsequently increase in both  
411 PV array capacity and battery stack capacity to further reduce the LCOE stan-  
412 dard deviation (and thus increase in SSR mean). For these designs, the LCOE  
413 standard deviation is significantly characterized by the uncertainty related to  
414 the battery (e.g. total Sobol' index up to 16% in the variable market conditions  
415 scenario for the dwelling, Figure 3). Therefore, improving the battery lifetime  
416 estimation is considered an effective approach to reduce the LCOE standard  
417 deviation of these designs with an external measure.

418 For the dwelling, a PV-battery configuration defines the robust design which  
419 achieves an SSR mean of 54% in the variable market conditions scenario and  
420 an SSR mean of 57% in the fixed market conditions scenario. Consequently,  
421 from this point, improving the SSR mean leads to an increase in LCOE stan-  
422 dard deviation due to the significant increase in system capacity, from which

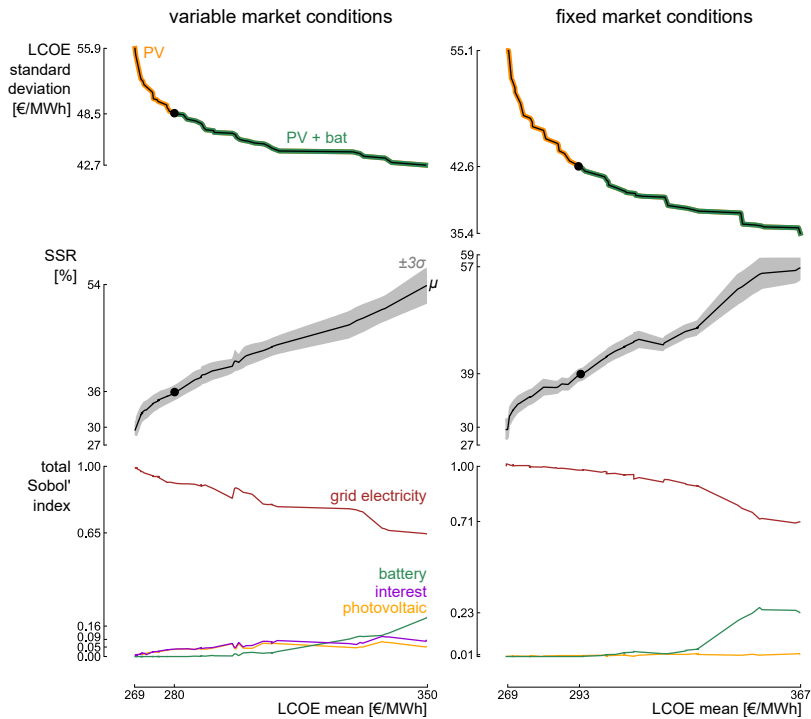

Figure 3: For the dwelling, the Pareto front illustrates that a trade-off exists between minimizing the Levelized Cost Of Electricity (LCOE) mean and LCOE standard deviation. Reducing the LCOE standard deviation cost-efficiently is suggested by subsequently expanding a PV array and battery stack. This system capacity evolution improves the mean Self-Sufficiency Ratio (SSR) and consequently reduces the importance of the grid price uncertainty. Instead, the uncertainty related to the interest rate (in the variable market conditions scenario) and the battery stack gradually gain in importance in the LCOE variation.

the corresponding uncertainty overcompensates the reduction in the uncertainty related to grid electricity. As lower uncertainty is related to the system capacity in the fixed market conditions scenario (i.e. deterministic investment costs), the SSR mean for the robust design in this scenario is higher than for the robust design in the variable market scenario. Therefore, the LCOE standard deviation for the robust design in the fixed market conditions scenario (35.4 €/MWh) is lower than for the robust design characterized in the variable market scenario (42.7 €/MWh). For the community, the robust design includes both a battery stack and a hydrogen-based energy system (Figure 4), despite the large uncer-

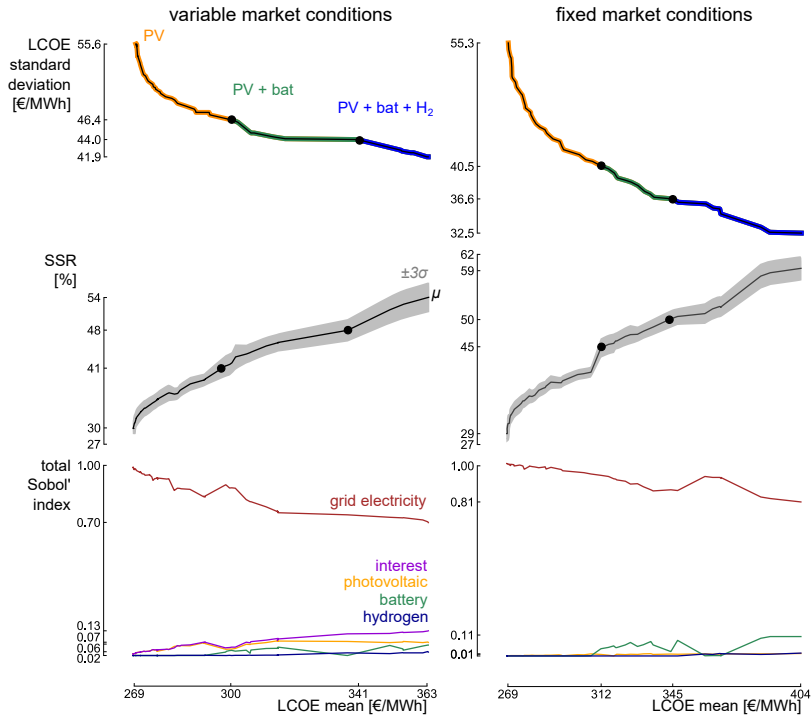

Figure 4: For the community, the Pareto front illustrates that a trade-off exists between minimizing the Levelized Cost of Electricity (LCOE) mean and LCOE standard deviation. Reducing the LCOE standard deviation cost-efficiently is suggested by subsequently expanding a PV array, battery stack and the hydrogen-based energy system. This system capacity evolution improves the mean Self-Sufficiency Ratio (SSR) and consequently reduces the importance of the grid price uncertainty. Instead, the uncertainty related to the interest rate (in the variable market conditions scenario) and the battery stack gradually gain in importance in the LCOE variation.

432 tainty related to the specific cost of the electrolyzer and fuel cell (e.g.  $\sigma_{\text{CAPEX}_{\text{elec}}} = 202 \text{ €/kW}$  as opposed to  $\sigma_{\text{CAPEX}_{\text{bat}}} = 73 \text{ €/kWh}$ ). The decoupling of power  
 433  
 434 (i.e. electrolyzer and fuel cell) and energy (i.e. hydrogen tank,  $\sigma_{\text{CAPEX}_{\text{tank}}} = 1.2 \text{ €/kWh}$ ) enables to curb the uncertainty related to the hydrogen-based en-  
 435  
 436 ergy system present in the LCOE standard deviation. Moreover, this flexible ca-  
 437  
 438 pacity setting of hydrogen storage results in the fact that the significant amount  
 439  
 440 of energy stored over a longer period can be achieved by solely increasing the  
 441  
 442 capacity of the hydrogen tank, as opposed to sizing the entire battery stack

440 for long-term energy storage. Conclusively, a PV-battery-hydrogen design pro-  
 441 vides a cost-efficient alternative for a large battery stack at moderate SSR and is  
 442 therefore configured as a robust alternative in both scenarios for the community.

9 443 *3.2. Comparison of stochastic performance*

10 444 Due to the trade-off between minimizing the LCOE mean and minimizing the  
11 LCOE standard deviation, each design out of the Pareto set of optimized designs  
12 445 carries an advantage in either average performance or robustness. To evaluate  
13 the overall stochastic performance, the CDF is constructed for three representa-  
14 446 tive optimized designs: the PV design that achieves the lowest LCOE mean, the  
15 447 PV-battery design that achieves the lowest LCOE mean among the proposed  
16 448 PV-battery designs and a robust design, which corresponds to the lowest LCOE  
17 449 standard deviation for the dwelling (Table 1) and for the community (Table 2).  
18 450 Among these designs, the PV design achieves the highest probability that in  
19 451 reality, the resulting LCOE over the lifetime will be lower than any predefined  
20 452 LCOE upper limit for the dwelling and community (yellow CDF in Figure 5 and  
21 453 Figure 6, respectively). To illustrate in a variable market conditions scenario, if  
22 454 the dwelling owner predefines an LCOE upper limit of 250 €/MWh to ensure an  
23 455 affordable cost of electricity, the PV design provides a probability of 44 % that  
24 456 the LCOE in reality will be below or equal to that upper limit. Alternatively, a  
25 457 lower probability that the real LCOE will be below this upper limit is achieved  
26 458 by the PV-battery design (33 %) and by full grid-dependency (24 %). However,  
27 459 when the upper limit value is determined higher or equal to 350 €/MWh in the  
28 460 variable market conditions scenario (374 €/MWh in the fixed market conditions  
29 461 scenario), the PV-battery design achieves a similar probability of resulting in an  
30 462 LCOE below the upper limit as the PV design. This observation is explained by  
31 463 the lower LCOE standard deviation of the PV-battery design, which steepens  
32 464 the corresponding CDF and therefore realises the intersection between the PV  
33 465 and PV-battery CDF, despite the larger LCOE mean of the PV-battery design.

34 466 The PV design achieves a rather low SSR mean (30 %), which makes this  
35 467 design vulnerable to grid behavior, fluctuating electricity prices and potential  
36 468 power cuts. Moreover, operating over a higher SSR threshold reduces the risk  
37 469 of black-out, as it avoids the simultaneous power extraction from the grid of  
38 470 different demand types. Therefore, the PV-battery design and robust design are  
39 471 of interest when operating over a larger SSR threshold is preferred (Figure 7 for  
40 472  
41 473

Figure 5: The Cumulative Density Functions (CDF) of three optimized designs and full grid-dependency for the dwelling. The intersection point between two CDFs illustrates the minimum LCOE upper limit that has to be defined, in order for the optimized design to achieve a higher probability than full grid-dependency to achieve an LCOE below this upper limit in reality.

Figure 6: The Cumulative Density Functions (CDF) of three optimized designs and full grid-dependency for the community. The intersection point between two CDFs illustrates the minimum LCOE upper limit that has to be defined, in order for the optimized design to achieve a higher probability than full grid-dependency to achieve an LCOE below this upper limit in reality.

the dwelling and Figure 8 for the community). To illustrate for the dwelling in a variable market scenario, the PV-battery design with the lowest LCOE mean achieves an SSR mean of 36 %, while the robust PV-battery design achieves an SSR mean of 54 %.

When operating over a higher SSR threshold is considered, the performance of the PV-battery design (green CDF in Figure 5 and Figure 6) is of interest and can be compared with full grid-dependency (red CDF in Figure 5 and Figure 6). In this comparison, the preferred design depends on the predefined LCOE upper

Figure 7: For the dwelling, the probability density functions of the SSR for three optimized designs illustrate the different SSR thresholds over which the designs operate.

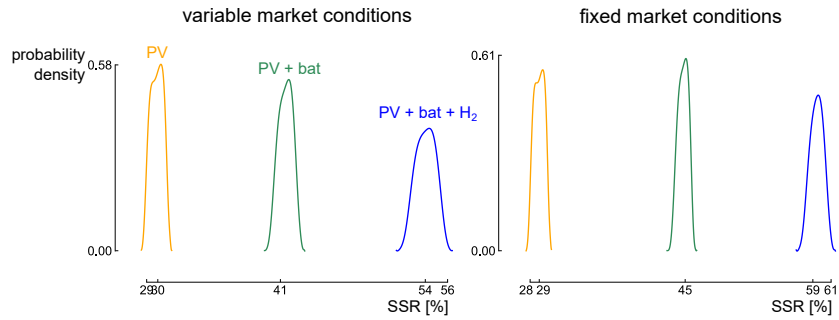

Figure 8: For the community, the probability density functions of the SSR for three optimized designs illustrate the different SSR thresholds over which the designs operate.

limit (and thus on the financial flexibility of the owner). To illustrate for the dwelling in the variable market conditions scenario, both the PV-battery design and full grid-dependency result in a probability of 16 % that the LCOE in reality will be below or equal to 231 €/MWh. If the LCOE upper limit is estimated even lower by the building owner to ensure an affordable cost of electricity, full grid-dependency results in a higher probability of ending up below the upper limit than the PV-battery design: e.g. full grid-dependency achieves a probability of 6 % that the LCOE in reality will be below 200 €/MWh, while the PV-battery design ensures a probability of only 1 %. Instead, if the LCOE upper limit is set higher than 231 €/MWh, the PV-battery design ensures a higher probability: e.g. full grid-dependency results in a probability of 49 % that the LCOE in reality will be below or equal to 300 €/MWh, while the PV-battery design ensures a

1  
2  
3  
4  
5  
6  
7  
8  
9 494 probability of 68 %. Conclusively, when the household projects an LCOE of at  
10 495 least 231 €/MWh as a maximum to ensure an affordable cost of electricity, the  
11  
12 496 PV-battery design provides a higher probability of complying with this upper  
13  
14 497 limit than full grid-dependency. Similar results are presented for the community.

15 498 Despite the lowest LCOE standard deviation, the CDF of the robust designs  
16  
17 499 do not intersect with the other evaluated optimized designs and is therefore only  
18  
19 500 of interest when operating over a larger SSR threshold. If so, then the robust  
20 501 PV-battery design for the dwelling (dark green CDF in Figure 5) proves to be  
21  
22 502 beneficial over full grid-dependency when the LCOE upper limit is set above  
23 503 384 €/MWh in the variable market conditions scenario and above 405 €/MWh  
24  
25 504 in the fixed market conditions scenario. For the community, a PV-battery-  
26 505 hydrogen configuration is characterized as a robust design (blue CDF in Fig-  
27  
28 506 ure 6). This design is beneficial over full grid-dependency when the LCOE upper  
29  
30 507 limit is defined higher than 414 €/MWh in the variable market conditions sce-  
31 508 nario and higher than 456 €/MWh in the the fixed market conditions scenario.  
32  
33 509 Consequently, a PV-battery-hydrogen design presents a cost-competitive alter-  
34 510 native over full grid-dependency and operates over a significant SSR threshold  
35  
36 511 ( $\geq 54\%$ ), which reduces the risk of black-out and power cuts.

#### 37 38 39 512 **4. Conclusion**

40  
41 513 The robust design optimization method illustrates a trade-off between min-  
42 514 imizing the levelized cost of electricity mean and minimizing the standard de-  
43 515 viation for a dwelling and a community. A photovoltaic array achieves the  
44 516 lowest levelized cost of electricity mean (i.e. 269 €/MWh). Additionally, such  
45 517 a system ensures the highest probability that the levelized cost of electric-  
46 518 ity in reality will be below an upper limit, which has been predicted by the  
47 519 system owner to ensure an affordable cost of electricity. Nevertheless, the  
48 520 proposed photovoltaic arrays remain primarily dependent on grid electricity  
49 521 (self – sufficiency ratio mean  $\approx 30\%$ ) and therefore subject to a significant stan-  
50  
51 522 dard deviation, risk of black-out and power cuts.

58  
59  
60  
61  
62  
63  
64  
65

523 Photovoltaic-battery designs reduce this grid-dependency by increasing the  
524 self-sufficiency ratio and therefore decrease the levelized cost of electricity stan-  
525 dard deviation. When operating over a higher self-sufficiency ratio is of interest,  
526 these photovoltaic-battery designs can ensure a higher probability than full grid-  
527 dependency to operate below the maximum affordable levelized cost of electricity  
528 predicted (e.g. 231 €/MWh for a dwelling in a variable market scenario).

529 For a community, the robust design achieves a significant self-sufficiency ratio  
530 ( $\geq 54\%$ ) and includes both a battery stack and a hydrogen-based energy  
531 system. This design is least-sensitive to real-life uncertainty as the decoupling  
532 of hydrogen power and hydrogen energy enables to curb the contribution of  
533 the uncertainty related to the electrolyzer and fuel cell in the levelized cost  
534 of electricity uncertainty. Moreover, these designs prove beneficial over full  
535 grid-dependency when the maximum allowed levelized cost of electricity is de-  
536 termined above 414 €/MWh in the fixed market conditions scenario and above  
537 456 €/MWh in the variable market conditions scenario. Conclusively, depend-  
538 ing on the financial flexibility of the system owner, battery and hydrogen storage  
539 provide a higher probability of realizing a levelized cost of electricity below the  
540 maximum allowed levelized cost of electricity to ensure affordability than full-  
541 grid dependency. Future work will focus on the integration of different locations.  
542 Moreover, a heat demand will be included, to fully exploit the fuel cell capability.
