Conclusion: ATT demonstrated excellent accuracy for steatosis detection, comparable to CAP and superior to HRI. Importantly, combining B-mode ultrasound with ATT significantly improved the diagnostic sensitivity. These findings suggest that ATT has the potential to become a valuable non-invasive tool alongside ultrasound for early detection of hepatic steatosis, aiding in earlier intervention and improved patient outcomes.

COMPARING THE PROGNOSTIC VALUE FOR LIVER DISEASE SCREENING OF THREE LIVER FIBROSIS MARKERS IN THE WELSH POPULATION FROM 2000 TO 2017: A GENERAL POPULATION-BASED COHORT STUDY

T. Hill¹, J. West², C. Crooks¹, J. Morling²

Contact E-Mail Address: joe.west@nottingham.ac.uk

Introduction: To investigate the prognostic utility of three non-invasive liver fibrosis markers calculated opportunistically from routine blood tests in the Welsh primary care population for identification of those at risk of cirrhosis or hepatocellular carcinoma (HCC).

Aims & Methods: Using the Secure Anonymised Information Linkage (SAIL) Databank at Swansea University (2000-2017) we identified a cohort of people with opportunistic liver blood tests that allowed calculation of 3 commonly used liver fibrosis markers: the aspartate transaminase to alanine transaminase (AST/ALT) ratio, the AST to platelet ratio index (APRI) and the fibrosis-4 index (FIB-4). These markers were modelled as continuous measurements using fractional polynomial models. This allowed the absolute rates and 10-year cumulative incidence of cirrhosis/HCC to be calculated across a range of risk thresholds, and we could then compare their performance via decision curve analysis. In addition, we reassessed the performance of these markers in higher risk patient populations including those with diabetes, obesity, and those with a history of alcohol misuse.

Results: There were 204,753 people with available blood tests enabling calculation of FIB-4, APRI and AST/ALT. At the commonly utilised cut-points to detect advanced fibrosis/cirrhosis of 3.25, 1.5 and 1.0 for FIB-4, APRI and AST/ALT respectively, the 10-year risks of cirrhosis/HCC were 7%, 18% and <1%. Decision curve analysis demonstrated that the APRI has the greatest net benefit for detecting 10-year risk of cirrhosis/HCC in a general population when compared to the AST/ALT ratio or FIB-4. For example, at low threshold risks for cirrhosis of 1-3%, the APRI identifies more true positive cases via fewer referrals for further investigation compared to the FIB-4. If implemented at the 3% risk threshold, the APRI would generate 7,061 referrals for further investigation for every 100,000 patients screened and capture 53% of potential cirrhosis cases, with 6,579 (93%) of those referrals being false positives.

In the diabetic sub-group of 18,006 patients, the 10-year risks of cirrhosis at the cut-points of 3.25, 1.5 and 1.0 on the FIB-4, APRI and AST/ALT respectively were doubled at 14%, 34% and 2.5%. If we implemented the same 3% risk threshold in the above 100,000 pseudo-population but restricted to only the 8.8% who would be expected to have diabetes ($n = 8794$), the APRI would generate 1956 referrals and capture 115 (73%) of potential diabetic cirrhosis cases, with 1841 (94%) of those referrals being false positives.

Conclusion: Liver fibrosis markers in the general population are unlikely to be useful to identify those at later risk of cirrhosis or HCC, because the prognostic utility of the markers leads to too many false positive and false negative results. In higher risk populations, like those with diabetes, the markers had more acceptable sensitivity – i.e. identified more, true positives, and generated a similar proportion of unnecessary referrals. Combining liver fibrosis markers with another investigation in high-risk groups such as Fibroscan may therefore be feasible to reduce the number of false referrals whilst maximising opportunities to identify those at risk of severe liver disease.

²Paracelsus Medical University Salzburg, First Department of Medicine, Salzburg, Austria

Contact E-Mail Address: georg.semmler@meduniwien.ac.at

Introduction: The LiverRisk score has been developed as blood-based tool to estimate liver stiffness measurement (LSM) in the general population (i.e., in subjects without known chronic liver disease (CLD), and thus, detect compensated advanced chronic liver disease (cACLD; LSM ≥ 10 kPa) and stratify their risk of liver-related events. Notably, its utility in other settings is unclear as a one-size-fits-all blood-based test. We aimed to evaluate its diagnostic/prognostic performance in patients referred to specialized hepatology outpatient clinics (i.e., tertiary care).

Aims & Methods: Subjects with known/suspected CLD at first LSM (cohort-I, n=5897) or first referral & LSM (cohort-II, n=1558) were retrospectively included. Calibration/agreement of the LiverRisk score with LSM was assessed as well as its diagnostic accuracy for LSM-defined cACLD compared to FIB-4/APRI. Finally, its predictive performance for hepatic decompensation was evaluated.

Results: In cohort-I/II, mean age was 48.3/51.8 years, 44.2%/44.7% were female, predominant etiologies were viral hepatitis (51.8%)/MASLD (63.7%), median LSM was 6.9 [5.1-10.9]/ 5.8 [4.5-8.8] kPa, and 1690 (28.7%)/ 322 (20.7%) had cACLD.

Despite a moderate correlation (Pearson's r: 0.325/0.422), the LiverRisk score systematically underestimated LSM (mean difference according to the Bland-Altman-method: -2.9/-1.8 points $\pm$ kPa). Variation of observed differences was considerable (95%CI of agreement: 39.4 and 35.2

points $\pm$ kPa), and showed a clear pattern towards larger disagreement at higher values with lower LiverRisk score than LSM.

The diagnostic accuracy of the LiverRisk for cACLD (AUROC: 0.757 [95%CI: 0.744-0.770]/ 0.790 [95%CI: 0.762-0.819]) was comparable to FIB-4 (0.769/0.813) and APRI (0.747/0.765). The cut-off of 10 points $\pm$ kPa yielded an overall accuracy of 74.2%/81.2%, high specificity (91.9/93.4%), but low negative predictive value (76.6/84.5%) with false-negative results in 20.0%/13.5% in cohort-I/II, respectively.

In cohort-I, 208 (3.5%) patients developed hepatic decompensation (median follow-up: 4.7 years). The LiverRisk score showed a reasonable accuracy for predicting hepatic decompensation within 2 years (AUROC: 0.817); however, it was inferior to LSM (0.891, p<0.001) and FIB-4 (0.912, p<0.001). The strata of LiverRisk score (and of LSM/FIB-4) discriminated patient groups of distinct risks for hepatic decompensation.

Conclusion: While being a major step forward for screening subjects without known liver disease in primary care, the LiverRisk score was not superior (vs. FIB-4) for diagnosis of cACLD or (vs. FIB-4/LSM) for prediction of hepatic decompensation in a tertiary care setting, i.e., in cohorts with a higher pre-test probability of cACLD. Notably, FIB-4 even outperformed the LiverRisk score in terms of prognostic utility.

CANCER RISK IN FAMILY MEMBERS OF INDIVIDUALS WITH MASLD: A POPULATION-BASED MULTIGENERATIONAL COHORT STUDY

F. Ebrahimi¹, J. Sun², D. Bergman¹, J.F. Ludvigsson³

¹Karolinska Institute, Stockholm, Sweden, ²Karolinska Institutet, Stockholm, Sweden, ³Karolinska Institutet, Medical Epidemiology and Biostatistics, Stockholm, Sweden

Contact E-Mail Address: febrahimi@outlook.com

Introduction: Recent findings suggest a higher risk of progressive liver disease and hepatocellular cancer in first-degree relatives of individuals with metabolic dysfunction-associated steatotic liver disease (MASLD). The familial risk of extrahepatic cancer is, however, unclear.

Aims & Methods: We conducted a nationwide multigenerational cohort study involving all family members of Swedish adults with biopsy-proven MASLD (1969–2017) and of matched general population comparators.

We included 36,684 first-degree relatives (FDRs: parents, siblings, offspring) and 8,788 spouses of MASLD individuals as well as 190,501 FDRs and 44,694 spouses of matched comparators without previous diagnosis of any cancer. Cox proportional hazards models were used to calculate multivariable adjusted hazard ratios (aHR) and 95% CIs.

Results: Over a median of 24.6 years the incidence rate for any extrahepatic cancer was slightly higher in MASLD FDRs than in comparator FDRs (72.3 vs. 71.9/10,000 person years (PY); aHR 1.04, 95%CI, 1.01–1.08). They were also at slightly higher risk of cancer-related mortality (24.0 vs. 23.6/10,000PY; aHR 1.08, 95% CI, 1.01–1.16). Compared to FDRs of comparators, largest differences were observed in rates of esophagus/stomach cancer (1.8 vs. 1.5/10,000PY; aHR 1.26, 95% CI, 1.01–1.58) and lung cancer (4.9 vs. 4.3/10,000PY; aHR 1.18, 95% CI 1.03–1.35).

Across generations of FDRs, the risk of cancer was uniformly increased with no differences by relationship (i.e., parents, siblings, and offspring; p>0.05). MASLD spouses were also at a slightly increased risk of extrahepatic cancer (119.1 vs. 113.4/10,000PY; aHR 1.07, 95%CI, 1.00–1.14) and cancer-related mortality (43.9 vs. 38.8/10,000PY; aHR 1.21, 95%CI, 1.07–1.38).

Compared to spouses of comparators, largest differences were observed in rates of colorectal cancer (17.0 vs. 13.4/10,000PY; aHR 1.34, 95% CI, 1.15–1.56).

Conclusion: First-degree relatives and spouses of individuals with biopsy-proven MASLD were at slightly higher risks of incident extrahepatic cancers, suggesting that shared lifestyle factors may contribute to the associations. Absolute cancer risks for family members were low and thus do not motivate implementation of screening programs.

THE CONTRIBUTION OF THE MEDICAL EDUCATION OF THE PATIENT WITH METABOLIC-ASSOCIATED FATTY LIVER DISEASE ON THE THERAPEUTIC RESULTS

A.N. Gologan¹, M.K. Grumeza¹, D.S. Gologan¹, E. Gologan², G. Balan², G.-E. Gilca-Blanariu²

Contact E-Mail Address: gologanandrei18@yahoo.com

Introduction: Metabolic-associated fatty liver disease (MAFLD) requires complex treatment based on diet and lifestyle. The understanding of the disease by patients through medical education is an element that could bring them a therapeutic benefit. Since the process is time-consuming and medical factors all over the world are under pressure to use maximum time for diagnostic and therapeutic purposes, an important role can be played by the voluntary activity carried out by medical students, under the guidance of teaching staff, devoted to this purpose.

Aims & Methods: A group of 250 patients with MAFLD, non-cirrhotic, diagnosed in a gastroenterology outpatient clinic, were proposed to participate in an educational program consisting of 3 sessions of 2 hours of interactive course about MAFLD (including notions of anatomy, physiology, diagnosis, evolution, prognosis, complications, risks, treatment, follow-up) in order to appreciate the contribution of medical education to the effectiveness of treatment.

The patients did not receive medication but only recommendations regarding lifestyle changes and the Mediterranean diet. They were re-evaluated 6 months after the initial evaluation.

Results: Of the 250 patients, only 126 (50.4%) accepted participation in the educational plan after informed consent, a disappointing proportion; the subgroup of those who did not participate in the course was reported as a control group (the main reason of non-participation was the fact that most of these patients considered to have already enough knowledge about MAFLD), being also invited to be evaluate after 6 months.

Educational presentations were given by medical students under the guidance of teaching staff (power-point presentations and informative flyers designed to fix the knowledges about disease) and patients were clinically, laboratory, ultrasound and fibroscan evaluated by attending physicians.

Also a questionnaire about quality of life was completed by each patient. Finally, after 6 months, only 85 patients from the control group and 118 from the study group returned for the final evaluation.

The final evaluation focused on 4 elements: 1- changes in body mass (decrease of more than 7%), 2- liver ultrasonography (reduction of the degree of steatosis), 3- laboratory analyzes (liver and metabolic tests) and 4- quality of life. In the study group, significantly better results were ob-

tained for parameters 1, 3 and 4: (78%, 87.2%, 84.7%) compared to the reference group (38.8%, 54.1%, 62.3%) which confirms the fact that patient education is an important element in understanding the disease and its treatment. Only in parameter 2 (decrease of steatosis at ultrasonography) there were no significant differences between the two groups (50.8% vs 48.2%), probably due to the too short follow-up time of the patients.

Conclusion: Therapeutic education of patients with MAFLD can bring more efficiency to the treatment of the disease in non-cirrhotic patients, mainly on body mass control, liver laboratory tests and quality of life, if they accept to participate at educational program.

EFFECT OF CHOLECYSTECTOMY ON LIVER FAT AND FIBROSIS IN MAFLD PATIENTS. PROSPECTIVE STUDY

K. Amalou¹, H. Benmellouka¹, R. Rekab¹, K. Saidani¹

¹HCA, Gastroenterology, Algiers, Algeria

Contact E-Mail Address: amalou_kh@yahoo.fr

Introduction: MAFLD is highly prevalent worldwide. Experimental studies have shown that cholecystectomy(Chx) increases hepatic steatosis(HS) and is associated with NAFLD in large retrospective cohort studies.

Aims & Methods: Evaluate the effect of Chx on HS and fibrosis, to assess the prevalence of MAFLD and to identify its risk factors(RF) in this population.

213 MAFLD patients were included, divided into two groups Chx(n=103) and non-Chx(n=110). At least a 5 years follow-up is conducted.

Results: BMI increased in Chx group (30.15±4.08 to 31.58±4.64)Vs (31.90±4.07 to 30.03±4.16) in the control group(p<0.001). Median CAP increased from 300.77±47.42 to 314.17±44.7(Chx) and decreased from 325.06±41.74 to 296.36±56.51 (control)(p<0.01). HS/MRI moved from 14.22±8.64 and 18.55±8.57 at baseline to 15.98±7.93 and 13.88±8.12 at the end of the study(p<0.001). The biological scores of HS(FI,HSI and LAP) all progressed in the Chx group and regressed in the control group(p<0.001). The prevalence of HS was 42.38%(Chx).

RF associated with significant HS were metabolic syndrome(MS), Chx, HS/MRI and FI score. RF associated with advanced fibrosis are BARD score, stiffness and Chx. Stiffness, obesity, Chx, GGT and HS/MRI are associated with NASH lesions.

Conclusion: Chx increases HS and fibrosis. MAFLD prevalence in Chx group is higher than overall population.

Disclosure: Nothing to disclose.

Contact E-Mail Address: mohan.patil@postgrad.curtin.edu.au

Introduction: G-protein coupled receptor-119 (GPR119) agonism is known to modulate non-alcoholic fatty liver disease physiology. However, due to off-target effects, challenges remain for successful GPR119 agonist pharmacotherapy.

Designing a non-systemic drug candidate that locally targets gut-located receptors for incretin secretion is suggested as a safer approach to minimise conventional side effects. This strategy may potentially limit the direct action on pancreatic β -cells; however, chronic use may lead to beneficial outcomes.

We developed a novel small-molecule agent as an oleoyl-lysophosphatidylinositol derivative that stimulates intestinal glucagon-like peptide-1 (GLP-1) secretion by coupling with gut receptors at the orthosteric site.

Aims & Methods: The present study was designed to investigate the chronic impact of novel GPR119 agonist agent ps297 alone and in combination with Sitagliptin on liver health in high-fat diet (HFD)-induced obese mice.

Five-week-old healthy male C57BL6/J mice were fed with HFD for 20 weeks. Normal control mice were maintained on a standard chow diet. A dose-escalation protocol was followed during the treatment phase. Oral administration of the test compound commenced with an initial dose of 10 mg/kg/day for the first week, followed by weekly dose escalations of 10 mg/kg for the subsequent ten weeks until reaching a maximum dose concentration of 90 mg/kg/day. Sitagliptin was gavaged at a fixed dose of 20 mg/kg/day. Vehicle control mice received an equal volume of 0.25% carboxymethyl cellulose in water.

After ten weeks of treatment, blood samples were collected from each 4-hour fasted mice. Biochemical parameters including plasma glucose, triglycerides (TG), cholesterol (CHO), alanine aminotransferase (ALT), and aspartate transaminase (AST) were analysed using an automated analyser. Plasmatic concentrations of metabolic hormones were determined in a multiplex assay platform. Hepatic TG, CHO, and hydroxyproline concentrations were determined in frozen liver tissue samples by colourimetric assay. Liver histology was studied in tissue stored in 10% neutral buffered formalin. Hepatic ballooning was assessed in hematoxylin and eosin-stained sections, imaged using a slide scanner.

Results: Ten-week co-administration of compound ps297 with sitagliptin resulted in higher plasmatic GLP-1 levels compared to the HFD control arm, which led to a significant ($p<0.05$) reduction in fasting plasma glucose levels in this group. Moreover, combination group exhibited a significant reduction in liver weights ($p<0.0001$), plasma CHO ($p<0.05$), ALT ($p<0.0001$), and AST ($p<0.01$) levels. Furthermore, combination treatment showed a significant reduction in hepatic TG ($p<0.0001$) and CHO ($p<0.001$) concentrations compared to the HFD control group. Elevated hepatic hydroxyproline levels in HFD control mice were attenuated by combination treatment.

Additionally, the hepatic ballooning score was found to be significantly reduced in the combination treatment mice.

Conclusion: Sitagliptin combination of ps297, improved glucose homeostasis in HFD-fed obese mice. Additionally, a prominent improvement in liver health status was observed in this group, as evident by reductions in liver weight, plasma liver enzymes, hepatic TG and CHO, and hydroxyproline levels. These findings were further supported by liver histological examination.

The overall findings suggest the pharmacological potential of the GPR119 agonist compound ps297 in combination with gliptins to alleviate fatty liver disease, warranting further molecular investigation in disease-specific animal models.

Introduction: Liver cirrhosis (LC) is the end stage of liver fibrosis that leads to various critical conditions, including hepatic encephalopathy (HE). Although recent evidence indicates that liver fibrosis is reversible, there is no intervention to promote this recovery process to date. The gut microbiota is thought to be involved in the pathogenesis of LC and HE. Rifaximin (RFX), a nonabsorbable broad-spectrum antibiotic, is widely used for HE treatment. Although the efficacy of RFX for HE has been established, the underlying mechanism of the efficacy of RFX remains unclear, while this antibiotic is considered to affect the gut microbiome.

Since the microbial compositions are different between anatomical sites in the gastrointestinal (GI) tract, we hypothesized that the effects of RFX on the gut microbiome can vary among GI sites.

Hence, we conceived the present study investigating the impacts of RFX on the gut microbiome along the GI tract to clarify the mechanism of RFX as well as to explore the role of the gut microbiota in the pathophysiology of LC and HE.

Aims & Methods: To investigate the impact of RFX on the gut microbiota and clinical manifestations of LC, RFX was orally administered to a carbon tetrachloride (CCl_4)-induced LC murine model. Blood ammonia (NH_3) concentration, liver pathological findings, and endotoxin concentration in the portal vein were examined. In each GI site, bacterial loads using qPCR of the *Tuf* gene and the bacterial compositions with 16S rRNA gene amplicon sequencing were assessed. Shotgun metagenomic sequencing was performed for jejunal and ileal contents to analyze the functional pathways in the small intestinal microbiota. On the host side, the gene expressions of the intestinal mucosa were examined using qPCR. To explore the clinical efficacy of *A. muciniphila* as a microbial intervention, we orally adminis-

tered *A. muciniphila* ATCC BAA-835 (AKK) to the CCl₄-induced LC murine model. The analyses described above for investigating the impacts of RFX were also performed for animals.

Results: RFX administration improved blood NH₃ concentration, liver fibrosis, and endotoxin concentration in the portal vein. The 16S rRNA gene amplicon sequencing analyses showed that the changes in the bacterial compositions were larger in the small intestine (jejunum and ileum) compared to the cecum, colon, and stool. The genus-level analysis of the small intestinal microbiota demonstrated that increases in *Faecalibaculum*, *Akkermansia*, and *Muribaculaceae* were associated with the improvement of liver fibrosis. Shotgun metagenomic sequencing showed that RFX administration altered the metabolic functions of the small intestinal microbiota. On the host side, the mRNA expression levels of tight junction proteins, antimicrobial peptides, and toll-like receptors in the small intestinal mucosa were altered by RFX administration. In the analyses of a microbial intervention, AKK administration improved liver fibrosis and blood NH₃ concentration. In addition, AKK administration significantly changed the small intestinal bacterial compositions in the murine LC model. The mRNA expression levels of tight junction proteins, antimicrobial peptides, and toll-like receptors in the small intestinal mucosa were altered by AKK administration.

Conclusion: This study demonstrated that the small intestinal microbiota was involved in the pathophysiology of LC and HE and proposed a new concept of “small intestine-liver axis” in LC and HE. The present study also suggests that oral administration of *A. muciniphila* is promising as a microbial intervention for these pathological conditions.

NON-PANCREATIC HYPERLIPASEMIA: A PUZZLING CLINICAL ENTITY

K.E. Feher¹, D. Tornai¹, Z. Vitális¹, L. Dávida¹, N. Sipeki¹, M. Papp¹

¹University of Debrecen, Division of Gastroenterology, Department of Internal Medicine, Faculty of Medicine, Debrecen, Hungary

Contact E-Mail Address: feher.krisztina.eszter@med.unideb.hu

Introduction: Increased lipase level is a serological hallmark of the diagnosis of acute pancreatitis (AP) but can be detected in various other diseases associated with lipase leakage due to inflammation of organs surrounding the pancreas or reduced renal clearance and/or hepatic metabolism. This non-pancreatic hyperlipasemia (NPHL) is puzzling for attending physicians during the diagnostic procedure for AP. It would be clinically beneficial to identify the clinical and laboratory variables that hinder the accuracy of lipase diagnosis with the aim of improve it. A more precise description of the NPHL condition could potentially provide prognostic factors for adverse outcomes which is currently lacking.

Aims & Methods: We aimed to provide a detailed clinical and laboratory characterization of a large prospective NPHL patient cohort and assess parameters determining disease outcomes.

A Hungarian patient cohort with serum lipase levels at least three times higher than the upper limit of normal (ULN) was prospectively evaluated over 31 months. Patients were identified using daily electronic laboratory reports developed to support an ongoing observational, multicenter, prospective cohort study called the EASY trial (ISRCTN10525246) to establish a simple, easy, and accurate clinical scoring system for early prognostication of AP. Diagnosis of NPHL was established based on $\geq 3 \times$ ULN serum lipase level in the absence of abdominal pain or abdominal imaging results characteristic of pancreatitis.

Results: A total of 808 patients [male, $n = 420$ (52%); median age (IQR): 65 (51-75) years] were diagnosed with $\geq 3 \times$ ULN serum lipase levels. A total of 392 patients had AP, whereas 401 had NPHL with more than 20 different etiologies. Sepsis and acute kidney injury (AKI) were the most prevalent etiologies of NPHL (27.7% and 33.2%, respectively). The best discriminative cut-off value for lipase was ≥ 666 U/L (sensitivity, 71.4%; specificity, 88.8%). The presence of AKI or sepsis negatively affected the diagnostic performance of lipase. NPHL was associated with a higher in-hospital mortality than AP (22.4% vs 5.1%, $P < 0.001$). In multivariate binary logistic regression, not lipase but increased amylase level (> 244 U/L) and neutrophil-to-lymphocyte ratio (NLR) (> 10.37 , OR: 3.71, 95%CI: 2.006-6.863, $P < 0.001$), decreased albumin level, age, and presence of sepsis were independent risk factors for in-hospital mortality in NPHL.

Conclusion: NPHL is a common cause of lipase elevation and is associated with high mortality rates. Increased NLR value was associated with the highest mortality risk. The presence of sepsis/AKI significantly deteriorates the serological differentiation of AP from NPHL.

TRANSFORMING THE MANAGEMENT OF SEVERE ACUTE PANCREATITIS: A MULTIDISCIPLINARY TEAM'S IMPACT ON INTERVENTIONAL ENDOSCOPY TIMING AND FOLLOW-UP AT A TERTIARY HPB CENTRE

D. Baig¹, P. Ratna¹, T. Nagdee¹, M. Shibeika¹

¹Blackburn Teaching Hospital, Gastroenterology, Blackburn, United Kingdom

Contact E-Mail Address: daniyalbaig@doctors.org.uk

Introduction: Effective timing of endoscopic interventions and follow-ups is crucial in the management of severe acute pancreatitis. Implementing a multidisciplinary team (MDT) approach not only enhances this timing but also ensures consistent clinical care, providing rapid responses to complications and timely adjustments in treatment plans. This coordinated approach optimises recovery and improves patient outcomes by integrating timely diagnostics and interventions. The MDT's strategic involvement is vital for maintaining high standards of care and safety and ensuring consistent and effective treatment of severe acute pancreatitis.

Aims & Methods: This retrospective cohort study assessed the impact of a novel hub-and-spoke severe acute pancreatitis (SAP) multidisciplinary team (MDT) model at a tertiary hepato-pancreato-biliary (HPB) centre. The model, which included Gastroenterologists, Surgeons, Nurses, Dietitians, and Radiologists, focused on optimising clinical outcomes by enhancing the coordination of hospital transfers and precision in the timing of interventional endoscopies. The study compared patient outcomes before the MDT implementation (January 2022 to January 2023) and after (November 2023 to March 2024), to improve intervention scheduling and establish systematic follow-up protocols to ensure comprehensive care. The primary objective was to evaluate how the MDT model influenced the timing of interventions and follow-up procedures in severe acute pancreatitis management.

Results: This study evaluated clinical outcomes for acute pancreatitis across two cohorts, comprising 191 patients before the implementation of a multidisciplinary team (MDT) and 76 patients following the implementation. For the pre-MDT cohort, the aetiology of pancreatitis included gallstone-induced cases (n=50), alcohol-related (n=45), idiopathic (n=2), and unspecified (n=94), with 28.79% of the cohort having a history of gallstones. In the pre-MDT group, the scheduling of interventions lacked consistency. 10 patients required inpatient endoscopic procedures, with a median time from admission to intervention of 13.0 days and a mean time of 12.79 days.

Post MDT implementation, 7 patients required inpatient endoscopic procedures, with waiting times reduced to a median of 6.5 days and a mean of 6.3 days. All these inpatients (n=7/7) received their procedures within the first week. The median duration of hospital stays was reduced from 8 days (pre-MDT) to 5 days (post-MDT). Additionally, the proportion of inpatients discharged within the first week post-intervention increased from 30% (n=3/10) pre-MDT to 71.4% (n=5/7) post-MDT. The average clinic follow-up time decreased from 169 days pre-MDT to 43 days post-MDT. The median timing to outpatient endoscopy was reduced, with 68% of patients receiving it in a six-week window post-discharge.

Conclusion: The integration of a multidisciplinary team (MDT) has markedly improved the management of severe acute pancreatitis, enhancing the precision and efficiency of interventional endoscopies. This optimised coordination has reduced hospital stays and ensured timely interventions, significantly boosting patient outcomes. The MDT approach effectively addresses the complexities of the condition, transforming patient care with tailored and rapid treatment strategies.

Disclosure: No disclosures.

Introduction: Fistula formation in the gastrointestinal (GI) tract associated with walled-off necrosis (WON) may complicate the clinical course of patients with acute pancreatitis. Identifying prognostic factors for this complication would help optimise the treatment algorithm for patients with WON and improve clinical outcomes.

Aims & Methods: In our multicentre cohort of 76 patients receiving endoscopic ultrasound-guided pancreatic fluid drainage (EUS-PFD) for WON between 2010 and 2023, we identified 27 patients with a GI tract fistula and examined prognostic factors for the development of this complication. We additionally examined factors for a severe GI fistula defined as a requirement of surgical management or death from uncontrollable infection presumably due to the fistula.

Results: Among the 27 cases with a GI fistula, there were 12, 9, and 5 cases with a fistula in the colon, duodenum, and small intestine, respectively. No statistically significant differences were noted between the groups with and without a GI fistula in terms of age (median; 65 vs. 69 years, respectively), female sex (19% vs. 27%, respectively), aetiology of pancreatitis (alcohol / ERCP-related / gallstone, 28%/28%/20% vs. 28%/20%/26%, respectively), maximum WON diameter (14 cm vs. 14.5 cm, respectively), or ascites (26% vs. 35%). WON extension to the paracolic gutter or the pelvic cavity was associated with a higher risk of a GI fistula with odds ratios of 3.3 (95% confidence interval, 1.2-8.8) and 5.6 (95% confidence interval, 1.9-16.7), respectively. Fistulas occurring in the colon were more likely to be severe compared to those occurring in the other sites. Compared to patients with non-severe or no GI fistula, patients with a severe GI fistula were more likely to undergo a longer hospitalisation with medians of 165 days vs. 57 days ($P < 0.01$). In an investigation of treatment outcomes between colonic and non-colonic fistulas, non-colonic fistulas were successfully managed by EUS-PFD and supportive care in all cases compared to 67% in colonic fistulas ($P = 0.03$). All four cases with unsuccessful endoscopic management of a colonic fistula were characterised by a fistula size of > 5 mm or penetrating to the bladder. Among the four cases, three cases required surgical resection of the colon, and one case died of uncontrollable infection despite an attempt of endoscopic fistula closure with an over-the-scope clip.

Conclusion: In this multicentre cohort study, WON extending to the paracolic gutter or pelvic cavity was a risk factor for the incidence of a GI fistula, and colonic fistulas were associated with unfavourable clinical outcomes.

A substantial proportion of endoscopic treatment failures were noted in patients with a colonic fistula, suggesting the necessity of considering treatment strategies for this subpopulation (including the timing of salvage surgery).

Introduction: While understanding the cause is pivotal for managing acute pancreatitis (AP), there is currently no established protocol for determining its aetiology. Ongoing research aims to validate diagnostic protocols and integrate advanced tests for cases of idiopathic acute pancreatitis (IAP). This study evaluated current international opinion about diagnosis and follow-up of IAP.

Aims & Methods: An international survey was conducted through an online survey platform; the link was shared through social media, e-mails and conference presentations. Responses were collected anonymously. The 37 questions were developed by an international multidisciplinary team, part of a Pancreas2000 collaborative project.

Results: Respondents (n=247) were from over 35 countries; 39% of them had over 10 years of clinical experience; 73% were working in tertiary referral centres; 56% were gastroenterologists, 34% surgeons. An equal number of respondents (n=85, 34%) chose magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound (EUS) as the first

test ideally performed in case of no suspected aetiology for AP after basic tests. When both investigations were available in the respondents' centre, 44% chose other tests, 30% MRCP and 27% EUS. If there is no evidence of biliary aetiology, 79% of respondents would not perform cholecystectomy; the rest would choose recurrent AP and a history of elevated liver enzymes as main indications. No correlation was found when comparing tertiary and non-tertiary centres in performing cholecystectomies, similarly when comparing centres with or without EUS availability.

Most respondents (90%) followed up on moderate and severe AP cases without an aetiology at index admission; 53% of centres followed up on all the IAP cases after first discharge. The follow-up was mostly done by gastroenterologists (62%); 33% of specialists would conduct a follow-up visit every 6 months, while 17% wouldn't recommend follow-up visits.

Conclusion: This international survey highlights the lack of standardisation for diagnosis and follow-up of IAP. Although MRCP and EUS were ideally chosen as first options in IAP diagnosis, respondents chose other investigations in their practice even when both were available. Only half of the centres schedule visits, showing a lack of consensus regarding follow-up. There is a need for international standardisation for diagnosis and follow-up of IAP.

Disclosure: Nothing to disclose.

Contact E-Mail Address: vsingh1@jhmi.edu

Introduction: Immunoglobulin G4-related disease (IgG4-RD) is an immune-mediated fibroinflammatory disorder that often affects multiple organs. Glucocorticoids (GCs) are often used first-line for the treatment of IgG4-RD.¹ Despite their therapeutic benefits, long-term GC use is known to be associated with toxicities that can affect several organ systems.¹ While the association between GC exposure and toxicities has been well characterized in other conditions, little is known about the real-world use of GCs and the associated clinical burden in the context of IgG4-RD.

Aims & Methods: Commercially insured adults (age ≥18 years) diagnosed with IgG4-RD were identified in the IQVIA PharMetrics® Plus database (01/01/2011-06/30/2022) using a validated algorithm. This algorithm considered IgG4-RD-related diagnoses, prescription medication fills, and medical procedures.²

The index date was defined as the first observed IgG4-RD-related diagnosis code, and the baseline and follow-up periods were defined as the 12 months before and after the index date, respectively. GC use during the follow-up period was calculated as the total cumulative prednisone equivalent dose divided by 365 days.

Patients were classified into two mutually exclusive cohorts based on GC use. The low GC use cohort comprised patients with a mean GC dose of <5 mg/day, including patients with no GC use; the high GC use cohort comprised those with a mean GC dose of ≥5 mg/day. Incident GC toxicities were defined as toxicities with ≥1 diagnosis during the follow-up period and no diagnosis during the baseline period. Demographic characteristics

were reported as of the index date; GC use and incident toxicities were reported during the follow-up period. Descriptive comparisons of incident toxicities between cohorts were analyzed using Chi-square tests.

Results: A total of 295 patients with IgG4-RD were identified, with 150 (50.8%) included in the low GC use cohort (mean age 48.9 years, 55.3% female) and 145 (49.2%) in the high GC use cohort (mean age 50.8 years, 45.5% female). In the first year after diagnosis, most patients (84.1%) received ≥ 1 GC fill, with a mean of 4.1 fills, corresponding to 3.9 months of treatment.

Patients in the low GC use cohort received a mean of 1.8 fills, corresponding to 1.4 months of treatment or a mean dose of 1.4 mg/day over the 12-month follow-up period. Patients in the high GC use cohort received 6.4 fills, corresponding to 6.5 months of treatments or a mean dose of 12.0 mg/day over the follow-up period.

Higher GC use was associated with higher rates of incident GC toxicities, such that patients in the high GC use cohort had a greater mean number of GC toxicities (1.8 vs. 1.2; $p < 0.01$) and were more likely to have ≥ 3 toxicities (29.0% vs. 13.3%; $p < 0.01$) than the low GC use cohort. In particular, cardiovascular (29.0% vs. 18.7%; $p = 0.04$), gastrointestinal (29.7% vs. 16.0%; $p < 0.01$), and infectious (31.0% vs. 17.3%; $p < 0.01$) toxicities were more commonly observed among patients with high GC use than low GC use.

Conclusion: In the first year after diagnosis, patients with IgG4-RD experienced a substantial GC burden, as evidenced by nearly half of them exposed to high GC use. Higher GC use was associated with an increased incidence of GC toxicities across multiple organ systems. These findings suggest an unmet need for safe and effective treatments to mitigate prolonged exposure to GCs and improve patient outcomes, particularly in the absence of targeted FDA-approved therapies for IgG4-RD.

Introduction: Proton pump inhibitors (PPI) are some of the most prescribed drugs. They are known to decrease pancreatic exocrine secretions and protect gastric mucosa. Therefore, there has been interest in the impact of their short-term in-hospital administration on acute pancreatitis outcomes, with disappointing results. However, it is yet to be described whether long-term use of PPI affects acute pancreatitis outcomes.

Aims & Methods: We aimed to investigate the association between chronic PPI use and short-term outcomes of AP.

In this retrospective observational study, we included all patients admitted with a primary diagnosis of acute pancreatitis between January 2008 and June 2021. Chronic medications including PPI were listed upon ad-

mission. Association between chronic PPI use and 30-day all-cause mortality was evaluated by univariate logistic regression.

Results: During the study period 2,308 patients were admitted due to acute pancreatitis. PPI were listed as a chronic medication for 708 of the patients. When compared to non-PPI patients, patients on chronic PPI were older (mean age 62.2 years vs. 53.7 years, $p < 0.001$), more likely to be female (51% vs. 46%, $p = 0.048$), with higher Charlson Comorbidity Index score (mean 4.1 vs. 2.2, $p < 0.001$) and higher Glasgow Imrie score (2.24 vs. 2, $p < 0.001$). Mortality rates at 30 days were 1.5% ($n = 11$) among chronic PPI users, compared to 4.6% ($n = 73$) among the non-PPI group, with an OR of 0.33 (95% CI, 0.16–0.6, $p < 0.001$).

Conclusion: Despite chronic PPI users being older with a greater comorbidity load, chronic PPI use was associated with significantly lower 30-day mortality rates among patients with acute pancreatitis.

Further studies examining this association, preferably prospective, are warranted.

Disclosure: Nothing to disclose.

EVALUATION OF THE EFFICACY AND SAFETY OF INTRAVENOUS LIDOCAINE IN THE ANALGESIC MANAGEMENT OF ACUTE PANCREATITIS: RESULTS OF A RETROSPECTIVE STUDY

L. Ghilardi¹, S. Hakim¹, F. Brazier¹, E. Nguyen-Khac¹, M. Fumery¹, C. Yzet¹

¹Amiens University Hospital, Gastroenterology, Amiens, France

Contact E-Mail Address: clara.yzet@gmail.com

Introduction: Pain in acute pancreatitis is the symptom to be treated urgently. There are currently no recommendations for analgesic management. Intravenous lidocaine has both analgesic and anti-inflammatory effects. Its use has never been evaluated for analgesia in acute pancreatitis. The aim of our study was therefore to evaluate the efficacy and safety of intravenous lidocaine in the management of acute pancreatitis resistant to level I and II analgesics.

Aims & Methods: We conducted a retrospective, monocentric study between January 2015 and December 2021. Patients visiting the emergency department for proven acute pancreatitis and presenting with pain resistant to group I and II analgesics, hospitalized in the hepato-gastroenterology department and treated with intravenous lidocaine, were included. Pain was assessed by retrospective collection of numerical pain scales (NPS) at the emergency department, and at each analgesic re-evaluation. Treatment efficacy was defined as the absence of need for a Level III analgesic (opioids).

Results: 154 patients, hospitalized in our gastroenterology unit for acute pancreatitis and presenting with pain refractory to level I and II analgesics treated with intravenous lidocaine were included. Patients were predominantly male, with a median age of 48.5 years [37.0; 58.0]. The main etiology of acute pancreatitis was ethylic in 36% of cases.

Acute necrotizing pancreatitis was present in 69% of patients. 44/154 patients received a bolus of opioid morphine in the emergency department before the administration of lidocaine. Lidocaine was prescribed in a continuous way at the dose of 2g/24h (intravenous administration with electric syringe).

The median NPS before prescription of lidocaine was 8.0 [7.00; 9.00]. Lidocaine treatment was effective in 88.7% of patients (136/154). 1.3% of patients experienced lidocaine-related adverse events such as skin rash and dysgeusia. In univariate analysis, patients requiring intensive care or developing an acute respiratory distress syndrome were significantly more likely to fail lidocaine (respectively OR = 5.83; CI [1.69; 20.06]; $p = 0.01$ and OR = 4.23; CI [1.44; 12.43]; $p = 0.009$).

Conclusion: Intravenous lidocaine administration appears to be effective and safe for pain control in 89% of patients failing to level I and II analgesia. Further prospective studies are needed to confirm these results.

Introduction: Abdominal pain is the cardinal symptom of acute pancreatitis (AP), often requiring opioid therapy. We aimed to investigate the dose-response relationship between exposure to opioids and the development of moderately severe and severe AP.

Aims & Methods: This was a post-hoc analysis of the prospective PAIN-AP database, which recruited patients with first-time AP from 118 centres across 27 countries between April 1 and June 30, 2022. From this database, we extracted baseline patient characteristics, post-pancreatitis outcomes and information regarding the dosage of opioid treatment. The morphine-equivalent doses (MEDs) of each opioid administered were calculated based on daily doses and duration of treatment and subsequently summarized into total cumulative MEDs for each patient. Using multivariable regression analysis, we identified risk factors for developing moderately severe or severe AP.

Results: The final cohort for this post-hoc analysis consisted of 1,030 AP patients receiving various doses of opioids (51% male; median age 54 (IQR, 40–69) years). The median pain severity on admission was 7 (IQR, 6–8), and in 504 (50%) patients, the pre-admission duration of pain was more than 24 hours. Most patients (78%) had mild AP, whereas 14% and 8% of patients developed moderately severe and severe AP. On multivariable analysis, a high burden of comorbidity (CCI>2), alcohol aetiology, pre-admission pain duration >24 hours and higher pain severity on admission were independent risk factors for moderately severe or severe AP. There was a significant increase in the risk of moderately severe or severe AP, per mg MED (OR 1.00 (95% CI, 1.00–1.00), P=0.039). Accordingly, receiving >40 mg MED (compared to <10 mg MED) increased the risk of moderately severe or severe AP (OR, 3.51 (95% CI, 2.09–5.93), P<0.001).

Conclusion: The association between opioid exposure and severity of AP was dose dependent. Further studies are warranted to explore this association as this may have clinical implications for pain management in AP.

Disclosure: Nothing to disclose.

DIAGNOSTIC ACCURACY OF ENDOSCOPIC ULTRASOUND GUIDED SHEAR-WAVE ELASTOGRAPHY FOR EARLY CHRONIC PANCREATITIS: A PROPENSITY SCORE MATCHED ANALYSIS

S. Shintani¹, O. Inatomi¹

¹Shiga University of Medical Science, Division of Gastroenterology, Otsu, Japan

Contact E-Mail Address: ss0513@belle.shiga-med.ac.jp

Introduction: Early chronic pancreatitis is a preliminary stage of chronic pancreatitis in “Mechanistic Definition”. However, the diagnostic criteria consist of subjective factors. Endoscopic ultrasound guided shear-wave elastography (EUS-SWE) is a novel imaging modality for the quantification of tissue stiffness. In this study, objective clinical features of ECP patients were examined using EUS-SWE.

Aims & Methods: We selected 34 patients in the ECP group and 53 patients in the normal group who underwent EUS-SWE from April 2020 to December 2021. ECP was diagnosed by JPN criteria in 2019. We used propensity score matching with age and sex, and 22 patients in each group were included in the evaluation. Elastic velocity measured by EUS-SWE (Vs, m/s) in the pancreatic body at least 5 measurements were examined. Each Vs value had a reliability measurement (VsN, %) and >50% was considered reliable. ALOKA ARIETTA 850 (FUJIFILM, Tokyo, Japan) and GF-UCT260 (Olympus, Tokyo, Japan) were used.

Results: The patients were 14 (63.6%) males with a mean age of 66.6 years in both groups. Type 2 diabetes mellitus was observed 18.1% in the ECP group and 22.7% in the normal group, history of alcohol consumption (>60g/day) was 36.4% and 9.1%, respectively. Clinical signs included 90.9% of abdominal pain, 18.2% of a history of acute pancreatitis, and 22.7% of pancreatic exocrine insufficiency in the ECP group. In addition, EUS findings showed 100% of Hyperechoic foci and strands, 54.5% of Lobularity, 68.2% of Hyperechoic duct wall, and 50% of Dilated side branch. The overall kappa values (95% CI) of interobserver reliability (IOR) for each EUS findings was as follows; hyperechoic foci and strands: 0.95 (0.86–1.0), lobularity: 0.67 (0.40–0.94), hyperechoic main duct margin: 0.68 (0.43–0.92), dilated branch ducts: 0.56 (0.27–0.86). Vs values were 2.21±0.56m/s in the ECP group and 1.69±0.36m/s in the normal group, which were significantly higher in the ECP group (p<0.001). The area under the curve for ECP diagnosis was 0.82 (cut off: 2.10, 95%CI: 0.69–0.94). However, Vs values were not useful as a predictor of type 2 diabetes or pancreatic exocrine insufficiency (p>0.05). There was a positive correlation between Vs values and the number of EUS criteria (rs=0.63, p<0.001). In multivariate analysis, history of acute pancreatitis and EUS score (≥2 criteria) were independent factors to increase Vs value.

Conclusion: The tissue velocity evaluated by EUS-SWE showed high elasticity in ECP compared to the normal pancreas. Furthermore, the Vs value was strongly correlated with EUS findings.

Disclosure: Nothing to disclose.

Introduction: Liquid biopsy in patients with pancreatic ductal adenocarcinoma (PDAC) has been challenged by the limited information obtained from systemic circulation (SC). Circulating Tumour Cells (CTCs) in portal circulation (PC) are deemed to be biologically relevant and potentially carrying prognostic significance, despite mostly been evaluated during surgery.

Aims & Methods: This prospective, single-centre, interventional study enrolled PDAC patients to assess the feasibility and safety of EUS-guided transgastric and transhepatic Portal Vein sampling (EUS-PVS) for isolating, enumerating, and characterizing CTCs. PC and paired SC samples underwent microfluidic enrichment and dielectrophoretic (DEP) single-cell sorting based on immunostaining for epithelial and mesenchymal biomarkers. Targeted next-generation KRAS sequencing was performed on CTC subpopulations in a subset of patients.

Results: Between May 2022 and October 2023, 20 PDAC patients (25% metastatic) underwent EUS-PVS with 100% feasibility and safety. CTCs were isolated in all patients from both districts, but the total CTC concentration was significantly higher in PC compared to SC (8.1 [5.8-21.3] vs. 4.1 [2.3-6] / 7.5 ml of blood, $p=0.01$), particularly for mesenchymal CTCs. No associations with baseline clinical variables or disease stage were observed. A subset of CTCs exhibited KRAS codon 12 mutations, undetected in paired white blood cells.

Conclusion: EUS-PVS is a feasible, safe, and effective method for portal blood sampling, supporting subsequent molecular investigations. Despite more sensitive enrichment modalities enhance the yield of peripheral CTCs evaluation, portal circulation remains more informative, especially for detecting epithelial-to-mesenchymal transition events. DEP single-cell sorting was feasible in all patients, providing libraries of viable cells with specific 100%-pure phenotypes, potentially suitable for downstream molecular applications.

ENDOSCOPIC VACUUM THERAPY OUTPERFORMS STENTS FOR UPPER GASTROINTESTINAL SURGICAL LEAKS AND FISTULAE: A NEW GOLD STANDARD ON THE HORIZON

D. Feijó¹, M. Costa¹, A. Silva¹, C. Chaves¹, E. Gravito-Soares¹, M. Gravito-Soares¹, P. Amaro¹, C. Agostinho¹, M. Ferreira¹, P. Narra Figueiredo¹

Introduction: Upper gastrointestinal tract leaks and fistulae following surgery present significant challenges, associated with high morbidity and mortality. Self-expanding metal stents (SEMS) have conventionally been utilized as the primary endoscopic treatment. However, endoscopic vacuum therapy (EVT) has emerged as a promising alternative.

Aims & Methods: This study aims to compare the efficacy and safety of EVT against SEMS in managing postoperative upper gastrointestinal tract surgical leaks/fistulae. We included 61 patients, 18 of whom underwent EVT from 2022-2024, and 43 who received SEMS treatment from 2014-2024. Demographic data, clinical characteristics, and treatment outcomes were retrospectively analyzed. Success rate, defined as complete closure of the leak/fistulae, as well as rates of complications, readmission, and mortality were compared between the two endoscopic modalities.

Results: There were no statistically significant differences regarding distribution by gender, age, benign vs malignant disease, time from surgery to endoscopic treatment and leak size ($p>0.05$). Larger leak size was associated with significantly lower likelihood of closure ($p=0.025$). EVT demonstrated a remarkable success rate, achieving complete closure of the leaks/fistulae in 94.4%, compared to 55.8% success with SEMS ($p<0.001$). EVT was associated with less endoscopic adjuvant therapy (22.2% vs. 46.5%, $p=0.009$), despite a higher number of treatment sessions (4 vs. 2, $p<0.001$). SEMS patients experienced higher rates of technique-related complications (76.7% vs. 5.5%, $p<0.001$), readmission (55.8% vs. 0%, $p=0.016$) and mortality (34.9% vs. 11.1%, $p=0.059$), although deaths were not related to endoscopic treatment.

Conclusion: This study results indicate that endoscopic vacuum therapy (EVT) significantly outperforms self-expanding metal stents (SEMS) in treating postoperative upper gastrointestinal leaks and fistulae. EVT achieved a notably higher success rate in terms of complete leak/fistula closure compared to SEMS, while also showing fewer technique-related complications, readmissions, and lower mortality rates. These findings suggest that EVT may represent a safer and more effective approach to managing these complex postoperative complications, potentially redefining the standard of care. Given its benefits, EVT could become the new gold standard for these entities, leading to improved patient outcomes and reduced healthcare burdens. Further research with larger patient cohorts is recommended to solidify the evidence supporting EVT's superiority in this clinical context.

PERSONAL PROTECTIVE EQUIPMENT INTERVENTION TRIAL FOR OESOPHAGOGASTRODUODENOSCOPY (PEPTIDE): A RANDOMISED CONTROLLED TRIAL TO ASSESS THE MEDICAL STAFFS' OCCUPATIONAL EXPOSURE TO INFECTIOUS PARTICLES EXHALED BY PATIENTS DURING OESOPHAGOGASTRODUODENOSCOPY

Z. Yan¹, Y. Zhang¹, S. Zhang¹, M. Duan², A. Yang¹, L. Liu²

Contact E-Mail Address: NirvanaYn@outlook.com

Introduction: As an aerosol-generating procedure, oesophagogastroduodenoscopy (OGD) promotes the production and release of infectious particles exhaled by patients, which would result in occupational exposure of medical staff and community spread.

We conducted the first prospective two-arm RCT to quantify medical staff's multi-route exposure to infectious particles exhaled by patients during OGD and to determine the efficacy of personal protective equipment (PPE).

Aims & Methods: In the PEPTIDE trial (NCT05321056), enrolled patients were randomly allocated to either with (intervention group) or without (control group) PPE (surgical masks) in a 1:1 ratio. A 3D-print anthropomorphic model with respiratory morphology and function was used to simulate medical staff and was placed at a fixed position beside the patients during anesthetic OGD. The distance from the oral cavity of the patient to the oral cavity of the anthropomorphic model will be 0.8 ± 0.1 m, and the anthropomorphic model will wear or not wear a surgical mask, according to the group allocation of the participant being examined. 1.5 mL saline solution containing 3.0 mg Vitamin B₂ (VB₂) was dripped into each patient's buccal mucosa and all relevant events of the patient, such as sneezing, nausea, vomiting, and snoring and their time of occurrence during OGD, would be recorded.

After examination, potentially infectious particles labeled with VB₂ in the model's facial region (eyes) and respiratory tract (oronasal cavities, pharynx and small airway) would be sampled timely and the fluorescence intensity (FI) of each would be measured. The primary and secondary outcomes were the exhaled particle dosage at the model's airway and facial regions, respectively.

Results: 130 patients were enrolled and assigned randomly to the two groups with 65 each. A positive exposure is defined as the FI of each sample greater than 800 CPS. Based on this, 61.5% of the models in the control group (40 subjects) were positive, compared to 26.2% in the intervention group (17 subjects); the difference between the two groups is significant ($P < 0.001$). Notably, almost all of them appeared in the upper respiratory tract, except one from the eyes. The mean total inhalation dosage was $(5.74 \times 10^{-5} \pm 5.81 \times 10^{-5})$ and $(2.43 \times 10^{-5} \pm 4.80 \times 10^{-5})$ mg of VB₂ in the control group and intervention group, respectively ($P < 0.001$).

Besides, correlation analysis showed that the use of PPE ($P < 0.0001$) and the personal medical history (PMH) of rhinitis ($P = 0.045$) were both negatively correlated with exposure, while high Mallampati classifications ($P = 0.014$) and hiccups during OGD ($P = 0.036$) were positively correlated with exposure. Based on the 4 factors above, a predictive model was established with a sensitivity of 73.7%, a specificity of 71.2%, and an overall accuracy of 72.3%.

Conclusion: This RCT study found that OGD medical staff are at a certain risk of inhalation exposure to pathogens released from potential patients, while wearing a surgical mask can reduce it by 57.8% concerning exposure dose. In addition, the PMH of rhinitis is found to be a protective factor for occupational exposure, while a high Mallampati classification and hiccups are risk factors.

Introduction: Endoscopic ultrasound (EUS) has broadened its diagnostic and therapeutic scopes, as it is able to target lesions <3mm. High-frequency radial EUS-miniprobe exhibit procedural time reduction, improving image quality and maneuverability. EndoSound Vision System (EndoSound, Oregon, USA) is a new EUS (N-EUS) portable device that fastens onto a standard gastroscope, enabling a free working channel. It is an affordable alternative to conventional-EUS devices; and a promising opportunity to shorten the difficult EUS learning curve.

Aims & Methods: We aim to determine the feasibility and effectiveness of N-EUS in terms of anatomical structures appropriate identification in comparison with conventional-EUS. This prospective study included patients ≥ 18 years-old undergoing EUS evaluation in June-November 2023 by eight endoscopists from different institutions from South and North America. Patients underwent two consecutive procedures: First, a conventional EUS with a linear-array echoendoscope (Pentax EG38-J1OUT, Pentax Medical, Germany). Then, a different endoscopist performed EUS using the N-EUS coupled to a video gastroscope with therapeutic access

(EG29-i10, Pentax Medical, USA). A post-procedure ad-hoc survey was completed by the second endoscopist, to assess N-EUS acceptability in terms of endoscopists' experience using this device.

Results: Thirty-one patients underwent conventional EUS and N-EUS: 16/31 performed by first-time N-EUS users, 15/31 by endoscopists with prior N-EUS exposure, with median procedural times of 30 and 15 minutes, respectively ($p=.04$). Main EUS indication was chronic dyspepsia (35.5%). Identified structures during N-EUS were the liver/gallbladder/common bile duct (30/31, 96.8%), full pancreas (29/31, 93.5%), kidneys/left kidney (24/31, 77%; 13/15 endoscopists with prior exposure vs 11/16 first-time N-EUS users; $p<.001$), left adrenal gland (20/31, 64.5%). Gallbladder (GB) was unobserved in 8 cases, 7/8 had prior cholecystectomy. Evaluation position was 54.8% supine; 3/31 switched to left lateral. All procedures were completed with 100% clinical and technical success, requiring navigation changes in 51.6%, mainly in first-time N-EUS users ($p=.001$). FNB tissue sampling was achieved in 100% cases. Endoscopists' experience was predominantly described as "meeting clinical expectations". The ad-hoc survey showed high psychometrics, with homogeneity among surveyed endoscopists, without redundancy (Cronbach's alpha of .91), and a good construct validity (Kaiser-Meyer-Olkin Criterion of .728 and Bartlett's test p -value $=.0005$). When comparing both procedures, appropriate identification of GB or lack of, full pancreas, left/both kidneys and left adrenal gland was 31/31 vs 30/31, 31/31 vs 29/31, 31/31 vs 24/31 ($p=.0233$), and 29/31 vs 20/31 ($p=.0158$), respectively. Considering conventional EUS as a gold standard, the observed agreement of N-EUS to identify these structures were 96.8%, 93.5%, 77.4% and 64.5%, correspondingly. Observed agreement for kidneys and left adrenal gland increased when sub-analyzing the cases assessed by endoscopists with prior N-EUS exposure: 81.2% and 76.9%, respectively.

Conclusion: N-EUS is a safe, effective, and feasible tool for EUS evaluation, with high acceptability by endoscopists. Prior ex-vivo training may be warranted for first-time N-EUS users.

EUS-GE: INITIAL SINGLE CENTER EXPERIENCE

A. Hujova¹, P. Macinga¹, J. Jarosova¹, J. Spicak¹, T. Hucl¹

¹*Institute of Clinical and Experimental Medicine, Hepatogastroenterology, Prague, Czech Republic*

Contact E-Mail Address: alzbeta.hujova@ikem.cz

Introduction: Endoscopic ultrasound-guided gastroenterostomy (EUS-GE) using a lumen-apposing metal stent (LAMS) is a novel endoscopic technique used to treat gastric outlet obstruction mostly caused by malignant disease such as pancreatic, gastric or biliary cancer. It is a technically challenging procedure with a high-risk of complications especially when performed by an endoscopist with limited experience.

Aims & Methods: We retrospectively analyzed our prospectively collected data of all EUS-GE performed in our center from 2021. Clinical success was defined by the gastric outlet obstruction scoring system (GOOSS). All procedures were done by one endoscopist with no previous experience with the technique.

Results: In total 30 patients were included in the study (16 men, 14 women, mean age 69 years (range 44-90)). The indication for EUS-GE was malignant disease (pancreatic cancer, cholangiocellular carcinoma, gastric cancer, gallbladder cancer, breast cancer, renal cancer, small bowel and liver cancer) in 28 cases and benign disease (chronic pancreatitis, aortic aneurysm) in 2 patients. The procedure was technically feasible in all but one patient (29/30, 96,7%). Clinical success when evaluated as restoration of solid oral intake was 86,2%

(25/29 patients) and 100% (29/29) when evaluated as restoration of at least liquid oral intake. The overall mean GOOSS achieved was 2,5 (1-3). Severe complications occurred in two patients (2/29, 6,9%). In one patient we experienced an unusual complication 6 months after the procedure when a gastrojejunocolic fistula developed, causing weight loss and fecal content vomiting. The fistula was successfully closed endoscopically. Another patient with a metastatic gastric cancer died one day after the intervention of a cardiac cause. Mean procedure time was 46 minutes (20-91) with no difference in mean time of the first and last five procedures. Mean survival post intervention was 135 days (1-560). No intervention for symptom recurrence was needed during a mean follow-up of 90 days.

Conclusion: EUS-GE is an efficient and safe technique in the treatment of gastric outlet obstruction even when performed by an endoscopist with no prior experience.

Introduction: EUS-guided gastroenterostomy (EUS-GE) is a novel and effective procedure for the management of malignant gastric outlet obstruction (GOO) with more durable results when compared to enteral stenting (ES). However, data comparing EUS-GE to ES in patients already treated with EUS-guided choledocoduodenostomy (EUS-CDS) for distal malignant biliary obstruction (DMBO) are lacking. We aimed to compare outcomes of EUS-GE and ES for the palliation of GOO in this specific population of patients.

Aims & Methods: A multicentre retrospective analysis of patients with DMBO treated by EUS-CDS and concomitant or subsequent GOO treated by EUS-GE or ES from 2016 to 2021 was conducted. Primary outcomes were overall AEs rate and dysfunction of the EUS-CDS after GOO treatment. Secondary outcomes included clinical success, technical success, procedure duration, length of hospital stay and relapse of GOO symptoms.

Results: 77 consecutive patients were included in the study: 25 patients underwent EUS-GE and 52 underwent ES. AEs rate and patency outcomes of the EUS-CDS after GOO treatment were comparable between the two groups (12,5% vs 17,3 %; p=0,74). No recurrence of GOO symptoms was registered in the EUS-GE group while 11,5 % of ES patients had symptoms recurrence after a mean follow-up period of 93,5 days.

Conclusion: EUS-GE and ES are both effective and safe for the palliation of GOO in patients already treated by EUS-CDS for DMBO with no difference in the biliary stent dysfunction rate and overall AEs. EUS-GE is associated with less recurrence of GOO symptoms.

Introduction: Combining antegrade (AGS) stenting and hepaticogastrotomy (HGS) is an increasingly used endoscopic ultrasound-guided intervention when stenting by endoscopic retrograde cholangiopancreatography (ERCP) is impossible. We comprehensively assessed the benefits and downsides of combined antegrade stenting and hepaticogastrotomy (HGAS).

Aims & Methods: The aim of our study was the justification of the addition of AGS during HGS. Five electronic databases were searched for studies on HGS with or without AGS from inception until December 2023. The odds ratio (OR) and pooled rates were used for single and two-arm comparisons with 95% confidence intervals (CI).

Results: The pooled technical and clinical success was 94% [CI:92-96%] and 88% [CI:84-91%] for HGS and 87% [CI:81-91%] and 94% [CI:89-97%] for HGAS, respectively. Pooled OR of HGAS and HGS showed an OR=0.25 [CI:0.03-2.34] for technical success and an OR=1.02 [CI:0.50-2.06] for clinical success.

The pooled adverse event rates were 20% [CI:16-25%] for HGS and 14% [CI:9-21%] for HGAS, whereas pooled OR showed an OR=0.94 [CI:0.14-6.38]. For re-intervention, an OR=0.37 [CI:0.27-0.52] was found. Time to stent dysfunction increased, HGAS 330 [CI: 280-Not reached] and HGS 209 [CI: 120-325] with no change in overall survival HGS 117 [CI: 91-151] and HGAS 147 [CI: 105-175].

Conclusion: The use of HGAS appears to increase clinical success and reduce the need for re-intervention. Overall adverse event rates were similar but bile leakage prevalence was decreased. Time to stent dysfunction seems to increase with no change in overall survival.

Disclosure: None to declare.

Introduction: Endoscopists are at increased risk of musculoskeletal injuries (MSI). Poor endoscopic posture is known to cause MSI. In this study, we systematically evaluated the ergonomic benefits of medical augmented reality glasses (ARG) in gastrointestinal endoscopy.

Aims & Methods: Screening gastroscopies were performed with and without ARG. The subjective experience was evaluated using a questionnaire-based NASA-Task Load Index (NASA-TLX). Biomechanical loads during endoscopy were captured using electromyography (EMG) sensors and motion tracking sensors. Perceived discomfort, muscle activity and body position were compared between ARG wearing group and non- ARG group.

Results: Five endoscopists performed total of 200 upper gastrointestinal endoscopies; 100 procedures in ARG group and 100 procedures in non-ARG group. Mean NASA-TLX scores of the participants were lower when ARG was used compared to those with conventional monitor. ARG wearing group exhibited improvements in physical demand, effort, and frustration scores compared to non ARG group. Muscle activation was significantly lower in ARG group compared to non ARG group in sternocleidomastoid and trapezius muscles. IMU analysis showed a significant reduction in the proportion of high risk positions of the neck and torso in the ARG group.

Conclusion: ARG was effective in improving the ergonomics of the examiner by correcting the bad posture of neck and torso during endoscopy. It reduces muscle fatigue and significantly corrects high risk posture that causes pain during endoscopy. The use of ARG in gastrointestinal endoscopy is expected to improve ergonomics for endoscopists.

Introduction: The ergonomics has been considered important in practicing surgical laparoscopy, and prior studies have shown significance of relevant factors e.g. operating room setup and design of surgical devices. However, little has been known in flexible endoscopy; How do endoscopists control flexible endoscopes? Which muscles are loaded during endoscopy? The deeper understanding of ergonomic aspects in flexible endoscopy is indispensable, since the number of endoscopies performed and its complexity are rapidly increasing.

Aims & Methods: We aimed to identify the differences of ergonomics between diagnostic endoscopy (EGD) and therapeutic endoscopy (ESD), by 1) multiple motion capture technology, and 2) wireless surface electromyography (EMG), in pre-clinical setting.

1) The multiple motion capture assessment

The control section of standard flexible endoscope (GIF-Q260J; Olympus, Tokyo, Japan), from the boot to the angulation knobs, was marked with 6 optical reflective markers. These markers were traced using a motion capture system (OptiTrack Flex13; NaturalPoint, OR) and the data were processed to generate 3-D coordinate data (The sternum manubrium of the endoscopist was setup as the coordinate origin; X: left-right axis, Y: cranio-caudal axis, Z: antero-posterior axis). EGD and ESD were performed with this motion capture system using live porcine models. For each endoscopist, mean±2SD for plotted coordinates from the origin was calculated in the three axes and described as a range of his/her arm/hand movement. The data were compared between EGD and ESD.

2) EMG assessment

Muscle activation of the left biceps brachii muscle, trapezius muscle, extensor carpi ulnaris muscle, flexor carpi radialis muscle, pronator teres muscle, thenar muscle, back neck muscle, and erector spinae muscle were recorded during endoscopic procedures using wireless surface EMG (BioLog DL-5500, DL-510A; S&ME, Tokyo, Japan). The maximal voluntary contraction (MVC) was obtained to normalize root-mean-square muscle activation as %MVC. We compared differences in muscle activity between EGD and ESD using %MVC.

Results: 1) The motion capture was performed on 15 board-certified endoscopists conducting EGD (n=13) and ESD (n=12). The movement range of endoscopist's left hand/arm holding endoscope is shown in the Table. On all three axes, the range of movement was significantly narrower during ESD than during EGD (X, p<0.001; Y, p=0.015; Z, p<0.001).

	EGD			ESD		
	X axis	Y axis	Z axis	X axis	Y axis	Z axis
Mean ± 2SD (cm)	-0.32±14.2	-24.3±11.0	12.8±11.6	-1.3±9.9	-22.8±9.8	7.9±8.9

2) The EMG was recorded during 15 EGDs and 8 ESDs. The %MVC was higher during ESD than EGD in an analysis including all muscles (LS-mean±SE; EGD, 28.9±1.5%; ESD, 34.1±2.6%; p=0.078). The comparison by each specific muscle showed that the extensor carpi ulnaris muscle (EGD, 34.6±3.5%; ESD, 47.8±5.8%; p=0.093) and the pronator teres muscle (EGD,

42.8±6.6%; ESD, 67.6±10.9%; p=0.092) had significantly larger %MVC during ESD (p<0.1 was considered statistically significant).

Conclusion: Our study has first shown that the range of endoscopis's movement was significantly narrower in therapeutic endoscopy than in diagnostic endoscopy. Furthermore, it was demonstrated that muscle activity, especially in left forearm muscles, was larger during therapeutic endoscopy. These data may help understanding the ergonomics in flexible endoscopy, and potentially contribute to optimize its working environment and further development of relevant medical devices.

Introduction: Loss of parietal cells causes the development of spasmolytic polypeptide-expressing metaplasia (SPEM) through transdifferentiation of chief cells. However, whether initial chief cell loss cause SPEN needs to be further investigated. Acidic mammalian chitinase (CHIA) belongs to the 18 glycosidase family and is expressed in epithelial cells in various organ, which can degrade chitin-containing pathogens, participate in Th2-mediated inflammation. CHIA is highly expressed in the chief cells, and our previous study showed that CHIA deficiency in the chief cells is the key event to induces SPEN and progress to gastric cancer, which is independent of parietal cell loss (Zhao et al., DDW 2023; Hu et al., KDDW 2021). However, the molecular role and mechanism of CHIA in the development of SPEN is need further investigated.

Aims & Methods: Aims: Explore new cellular origins and specific molecular mechanisms of SPEN occurrence.

Methods: PCR and single-cell sequencing (scRNA-seq) technology, histopathological and immunofluorescence (IF) with specific markers were performed in CHIA wild type (WT) mice and knockout (KO) mice. Multiple endoplasmic reticulum stress markers, macrophage polarization markers and cytokine-related markers were detected by qPCR in CHIA WT and KO.

Results: PCR and scRNA-seq technology data showed that increased M2 macrophage infiltration and SPEN formation, but remaining of parietal cells in CHIA KO mice, when compared to CHIA WT mice. Furthermore, deletion of CHIA in mice resulted in release of endoplasmic reticulum stress-triggered, including upregulation of endoplasmic reticulum stress markers (PERK, XBP-1, eIF2α/P-eIF2α, and GRP78), followed with upregulation of pyroptosis-related marker, including NLRP3, ACS, GSDMD, NEK7, Caspase1, Caspase11, IL-1β, and IL-18, as well as significantly increase-ment of IL33/IL-13 release. Moreover, Double immunofluorescence staining showed that upregulation and colocalization of NLRP3 and IL-33 induced M2 macrophage polarization markers, including F4/80 and CD163 in the gastric mucosal of CHIA KO mice. Notably, IF showed that CHIA deficiency caused the mucous neck cell marker SOX9 shifted from the cervical isthmus into the SPEN cells, and co-localized with the SPEN markers CD44v, TFF2 and MUC6, suggesting that the origin of SPEN cells may trans-differentiate from mucous neck cell after CHIA gene deletion.

Conclusion: CHIA deficiency in the chief cells promotes SPEN through the pyroptosis mediated M2 macrophage polarization. The origin of CHIA deficiency promotes injury may origin from the transdifferentiation of mucous neck mucus cells into SPEN cells.

NAD(P)H QUINONE OXIDOREDUCTASE 1 (NQO1) PREVENTS GASTROINTESTINAL EPITHELIUM AGAINST REDOX IMBALANCE AS A MOLECULAR TARGET OF ENDOGENOUS HYDROGEN SULFIDE (H₂S)-SIGNALING AND NOVEL OXIDATION-SENSITIVE H₂S-PRODRUGS

Introduction: NAD(P)H quinone oxidoreductase 1 (NQO1) is an oxidation-sensitive enzyme that protects cells against redox imbalance. Involvement of NQO1 in gastrointestinal (GI) health and disease has been poorly studied. Hydrogen sulfide (H₂S) is an endogenous and anti-oxidative molecule that exerts anti-oxidative activity due to the posttranslational persulfidation of proteins. Bioactivity of H₂S is related e.g. to the regulation of antioxidant response elements (AREs) in the nucleus that subsequently affect many molecular factors. We assume that this phenomenon could also include NQO1. Importantly, triggerable H₂S-prodrugs, activated by reactive oxygen species (ROS) are a new class and promising agents in therapeutic applications but remain poorly explored in GI pharmacology. Novel, click-and-release carbonyl sulfide/H₂S donor (Peroxy-TCM), in the presence of ROS is capable to rapidly release cytoprotective H₂S. Of note, oxidative stress and ROS generation have been linked to the development of Barrett's esophagus (BE) or acute gastric mucosal injuries.

Aims & Methods: Therefore, we verified the contribution of the interplay between NQO1 and H₂S-signaling in the pathogenesis of oxidation-dependent GI diseases. We assessed the therapeutic capacity of the novel "click-chemistry"-based pharmacology, implementing this approach in experimental gastroenterology.

Clinically, proteome profile and pathway-specific PSSH shifts were evaluated using recent chemoproteomic approach in 3 sets of endoscopic esophageal samples: BE, squamous segments exposed to gastroesophageal reflux (GERD), and squamous segments from patients w/o GERD. Experimentally, male Wistar rats were administered intragastrically (i.g.) with i) vehicle, ii) peroxy-TCM (4 mg/kg) as a novel ROS-activated COS/H₂S donor or iii) peroxy-CM, as a structural control w/o H₂S-releasing ability. Peroxy-TCM was also combined with pharmacological NQO1 inhibitor (dicumarol, applied i.g.). Next, animals underwent microsurgical ischemia/reperfusion (I/R), selectively targeting gastric mucosa. Gastric mucosal damage was assessed micro- and macroscopically. Bioavailability of H₂S and oxidative RNA damage reflected by 8-hydroxyguanosine (8-OHG) levels were assessed in gastric mucosa. Pathway-specific proteome changes in the gastric mucosa were evaluated using mass spectrometry-based proteomics.

Results: Clinically, NQO1 protein and its persulfidation was progressively increased at subsequent phases of BE pathogenesis. Experimentally, peroxy-TCM in contrast to its negative control, reduced gastric damage and RNA oxidation induced by I/R. Gastric mucosal I/R activated peroxy-TCM and evoked H₂S-release in gastric mucosa. Proteomic screening showed

that gastroprotective effect of peroxy-TCM was accompanied by the increased mucosal level of NQO1. Pharmacological inhibition of NQO1 attenuated beneficial effects of H₂S-prodrug.

Conclusion: NQO1 emerged as an important molecular target that contributes in anti-oxidative response of GI epithelium to pathology-driven redox imbalance. NQO1 and its persulfidation could be also considered as an early biomarker of BE development. NQO1 activity in gastric mucosa depends on the H₂S-bioavailability. Click-chemistry-based H₂S-therapeutics appeared here to selectively release this gaseous molecule in controllable-manner (only in the presence of ROS) when applied i.g. This therapeutic approach mechanistically activates gastric mucosal NQO1, increasing the ability of gastric epithelium to cope with oxidative stress. Introduction: Several factors are known to affect the clinical presentation of *Helicobacter pylori* (*H. pylori*) infection including bacterial virulence factors, intensity of the immune response of the host, host's genetic factors, as well as different environmental factors. Complex interactions between *H. pylori* and the host's immunological response result in the production of various cytokines (interferon- γ , tumor-necrosis factor α , interleukin-1 β , and interleukin-8) and reactive oxygen species (ROS) which lead to prolonged inflammation and subsequent damage to the gastric mucosa. Various inflammation mechanisms have been studied in *H. pylori* infection, including those related to the NF- κ B signaling pathway, ROS, and more recently NLRP3 inflammasome.

When it comes to the multifunctional family of glutathione transferase enzymes, glutathione S-transferase omega (GSTO) and pi (GSTP) are known for their antioxidant, as well as signaling activity. Specifically, the regulatory effects of GSTO and GSTP1, on NLRP3 inflammasome and NF- κ B signaling pathway, respectively, have been extensively studied.

Aims & Methods: Based on the known catalytic and signaling functions of GSTO and GSTP and their effect on both redox homeostasis and inflammation, we proposed a possible modifying role of GSTO and GSTP1 polymorphisms in the individual susceptibility towards the development of *H. pylori* infection. The distribution of polymorphisms in GSTO1 (rs4925), GSTO2 (rs156697), and GSTP1 (rs1695 and rs1138272) were assessed in 101 *H. pylori*-positive and 107 *H. pylori*-negative patients, emphasizing their individual and haplotype effects on disease development. Polymorphisms were determined by the appropriate qPCR method.

Results: The obtained results showed no influence of GSTO1 (rs4925) and GSTO2 (rs156697) polymorphisms on *H. pylori* infection development in both individual and haplotype analyses ($p>0.05$). However, individuals carrying variant GSTP1 (rs1695 and rs1138272) genotypes exhibit up to three times higher odds of *H. pylori* infection development, compared to those carrying referent alleles (Table 1).

GSTP1 rs1695 genotype	HP negative, n (%)	HP positive, n (%)	OR (95% CI)	p
*A/A	47 (44)	35 (35)	1 ^a	
*A/G	53 (50)	50 (49)	1.27 (0.71-2.27)	0.427
*G/G	7 (6)	16 (16)	3.07 (1.14-8.26)	0.026
*A/G + *G/G	60 (56)	66 (65)	1.47 (0.84-2.58)	0.172
GSTP1 rs1138272 genotype				
*C/C	92 (87)	74 (73)	1 ^a	
*C/T	14 (13)	22 (22)	1.95 (0.93-4.08)	0.075
*T/T	0 (0)	5 (5)	/	/
*C/T + *T/T	14 (13)	27 (27)	2.39 (1.17-4.89)	0.016

Table 1. Distribution of GSTP1 genotypes in *H. pylori*-positive and *H. pylori*-negative patients.

HP – *Helicobacter pylori*; OR – odds ratio; CI – confidence interval

These findings are confirmed by further haplotype analysis. Carriers of H3 haplotype, comprising GSTP1*G and GSTP1*T variant alleles were at more than a 3-fold increased risk of *H. pylori* infection development ($p=0.012$).

Conclusion: GSTP1 polymorphisms modify susceptibility to developing *H. pylori* infection. Further studies are needed to clarify the specific roles of glutathione transferases in innate and acquired immune response in the context of *H. pylori* infection development and maintenance.

Introduction: For autoimmune atrophic gastritis (AAG) two pathogenetic models are proposed: a pure autoimmune disorder or gastric autoimmunity triggered by *Helicobacter pylori* (Hp) infection. In AAG, the diagnosis of Hp infection with conventional methods is challenging due to oxyntic mucosa atrophy, hypochlorhydria, and gradual Hp clearance.

Formerly, Hp seropositivity in AAG with negative Hp histology was shown by Western blotting. A Hp multiplex serology assay allowing simultaneous detection of antibodies to several Hp proteins and virulence factors has not been used so far in sera of AAG pts to test for Hp exposure.

Aims & Methods: The aim was to assess seroreactivity against Hp proteins in AAG pts, Hp negative at histological evaluation of gastric biopsies and without history of Hp infection.

Single centre case-control study on 75 adults with histological AAG diagnosis, age 63 (18-88) yrs, F:M 2.4:1, parietal cell (PCA)-intrinsic factor auto-antibodies (IFA) positivity in 81.3%-41.3%. AAG pts were compared with 2 control groups: 62 healthy stomach subjects (HS), age 65.5 (23-90) yrs, F:M 1.1:1, and 16 controls with Hp-positive antral non-atrophic gastritis (NAHp), age 59.5 (31-78) yrs, F:M 1.7:1. All 153 subjects had gastroscopy with biopsies, according to the updated Sydney system, for clinical suspicion of AAG (anaemia or dyspepsia) or AAG follow-up. Frozen sera (-20°C) were analysed by Hp multiplex serology assay.

This assay is based on a glutathione-S-transferase (GST) capture immunosorbent assay combined with fluorescent bead technology measuring antibody responses to 13 Hp proteins (CagA, VacA, UreA, HP0875, NapA, HpaA, HyaA, HcpC, Cad, GroEL, HP0231, HP0305, HP1564). Median fluorescent intensity (MFI) values for each antigen were determined in a 1:1000 serum dilution. Seropositivity to individual antigens was defined as MFI above cut-off. Hp seropositivity was defined as being positive for >3 or more antigens.

Results: AAG pts showed a higher, but not significantly, Hp seropositivity than HS (n=16/21.3% vs n=6/9.7%, $p=0.06$), but a significantly lower seropositivity than NAHp (12/75%, $p<0.0001$). The number of participants positive to none of the Hp antigens was similar in AAG and HS

(n=22/29.3% vs n=24/38.7%, p=0.25), and significantly higher than in NAHp (n=1/6.2%, p=0.05). The number of seroreactive antigens was significantly higher in AAG than in HS (mean±SEM 2.2±0.3 vs 1.4±0.2, p=0.04), and lower than in NAHp (5.4±0.7, p<0.0001). Hp antigens seroreactive in >50% of the 16 Hp seropositive AAG pts included GroEL, NapA, CagA, HyaA, Catalase, HcpC, and HP1564; UreA and VacA were seropositive in 37.5%/16 seropositive AAG pts.

Severe corpus atrophy was significantly more frequent in the 22 AAG pts without any seroreactivity (0 Hp antigens) than in seropositives (p=0.019) suggesting more severe disease in pts never exposed to Hp. IFA positivity was nearly 2x in Hp seronegatives compared to seropositives (45.8% vs 25%, p=0.137) albeit not significant. An inverse relationship between anti-UreA and IFA titers was shown (Spearman's rho -0.25 (95%CI -0.46 to -0.03), p=0.03), suggesting an opposite trend of Hp immunoreactivity and gastric autoimmunity.

Conclusion: By Hp multiplex serology, 30% of histologically Hp negative AAG pts had complete absence of seroreactivity, likely belonging to the pure AAG type. In contrast, 20% of AAG pts showed exposure to Hp, indicating that infection might have played a role in triggering gastric autoimmunity. The remaining 50% of AAG pts showed a weak seropositivity, probably belonging to a grey zone, not definitively categorizable by this approach.

Introduction: Autoimmune atrophic gastritis (AAG) is an immune-mediated disorder characterized by corpus-restricted atrophy and pseudopyloric or intestinal metaplasia, associated with reduced hydrochloric acid and intrinsic factor production and heterogeneous clinical consequences. The aetiology of AAG is autoimmune, but the role of *Helicobacter pylori* (Hp) has been proposed, although not definitively proven.

A possible antigenic crossreactivity with H⁺,K⁺-ATPase, the main autoantigen in AAG, has been reported and Hp seropositivity has been described in histologically Hp negative AAG.

One study employed molecular biology techniques to characterize a cohort of AAG patients as definitively Hp naïve.

Aims & Methods: The aim was to assess the presence of Hp-related genes in corpus mucosa biopsies of pts with AAG and Hp-positive and negative ctr by using real-time PCR.

Single-centre, experimental molecular biology study on 55 pts with histologically diagnosed AAG, of whom at histology 52 were Hp negative (age 61.5, range 28-88 yrs, 75% F, 96.2% parietal cell (PCA) and 44.2% intrinsic factor antibodies (IFA) positive), while 3 were Hp positive (age 74,69,33 yrs; 1 F; all 3 PCA and 1 IFA positive). Ctr were 4 pts who underwent gastroscopy for non-ulcer dyspepsia, 2 with Hp-positive superficial antral gastritis (positive ctr), and 2 with a healthy stomach (negative ctr). Hp serology (ELISA or multiplex) was available from all pts.

DNA was extracted from formalin-fixed, paraffin-embedded (FFPE) tissue sections of corpus mucosa biopsies and real-time PCR was performed using specific probes for UreA, UreC, and CagA Hp related genes; 16sRNA and Beta2 microglobulin (B2M) specific probes were used as amplification ctr of bacterial and human DNA (real-time PCR cycle threshold (CT) >28<38).

Results: In 4(7.7%) of the 52 histologically Hp negative AAG pts, Hp-related genes were detected, in 4(7.7%) UreC, in 3(5.8%) UreA, and in 1(1.9%) CagA. All of them (3 F, aged 88,85,58,56 yrs) had positive Hp serology and PCA, only one was IFA-positive.

The detectability of B2M and bacterial 16sRNA genes did not differ in UreC-positive or UreC-negative pts (B2M CT mean 29.6±1.2 for UreC positives vs 29.7±1.4 for UreC negatives, p=0.99; 16sRNA gene CT mean 29.9±1.2 vs 29.4±1.2, p=0.27) indicating that the not-detectability of Hp-related genes was unrelated to reduced amounts of gastric bacterial or human DNA.

Hp serology was positive in all 4 histologically Hp-negative AAG pts positive for UreC compared to 5/48(10.4%) UreC negative pts (p<0.0001) indicating previous exposure. PCA were present in all 4 UreC positive AAG pts compared to 46/48(95.8%) of UreC negatives (p=0.68).

IFA positivity in UreC negatives was nearly 2x higher than that of UreC positives (45.8% vs 25%, p=0.42) without reaching significance. In 2/3 pts with histologically Hp-positive AAG, Hp-related genes could be detected; in the remaining patient, nor UreA, UreC neither CagA gene could be found (M, 69 yrs, no anemia, PCA-IFA-Hp serology positive).

Conclusion: In >90% of histologically Hp-negative and PCA or IFA positive AAG pts, Hp-related genes cannot be retrieved in the gastric mucosa. In 10% of these Hp-genes negative AAG pts, previous exposure to Hp can be testified by positive serology.

Hp-related genes can be detected in gastric biopsies in <10% of histologically Hp-negative AAG patients and positive Hp serology further confirms the role of Hp in this group.

These findings show that primary, Hp naive AAG is the more common type, but in a subset of pts, AAG seems to be secondary to Hp infection.

Introduction: Vonoprazan (VPZ) has been used in Japan since 2015 to eradicate *Helicobacter pylori*. The level of acid inhibition required for *H. pylori* eradication is a pH > 5.0, and VPZ treatment maintains this state for an extended period. Accordingly, VPZ reportedly has a higher eradication success rate than conventional proton pump inhibitors. However, the incidence and risk factors of gastric cancer (GC) as well as long-term prognosis after VPZ eradication of *H. pylori* remain unclear. Neutrophil-to-lymphocyte ratio (NLR) is an indicator of asymptomatic chronic inflammation. NLR was reported to reflect the balance between the tumor-promoting environment and the anti-tumor immune status.

Aims & Methods: This single-center cohort study included 934 consecutive patients who underwent *H. pylori* eradication using a VPZ regimen between February 2015 and June 2017. The patients were followed up for 5 years after *H. pylori* eradication. The trial was registered in the University Hospital Medical Information Network Clinical Trials Registry (UMIN000046308). The eradication regimen included VPZ 40 mg/day, amoxicillin 1500 mg/day, and clarithromycin 400 mg/day for 1 week for primary eradication and VPZ 40 mg/day, amoxicillin 1500 mg/day, and metronidazole 500 mg/day for 1 week for secondary eradication.

We examined the NLR at the time of eradication and investigated whether it could be a predictive marker of eradication success, risk of post-eradication GC development, and long-term prognosis.

Results: The study cohort included 57.3% men and had a mean age of 57.8 (interquartile range, 49-67) years. Of them, 3.2% had a history of GC resection. Two-thirds of all patients (59.0%, n=551) had open-type atrophy. The mean (standard deviation) NLR was 1.99 (1.20). The successful eradication rates were 92.6% (intention-to-treat) and 98.7% (per-protocol). Minor side effects (e.g., rash, diarrhea) occurred in 2.0% of all patients. A multivariate analysis showed that high NLR (odds ratio [OR], 2.96; p=0.004) was significantly associated with eradication failure. During the 5-year observation period, twelve cases of stage IA GC developed. The

3-year incidence rate was 0.87% and the 5-year incidence rate was 1.67%. The average time from eradication to diagnosis was 40.5 (6.1) months. A multivariate analysis showed that a high NLR (OR, 6.0; p=0.026), history of GC (OR, 6.9; p=0.011), and history of hypertension (OR, 5.8; p=0.016) were significantly associated with GC development. In contrast, age ≥ 70 years (p=0.402) and open-type atrophy (p=0.120) were not significant factors of GC development. A receiver operating characteristic curve showed that the optimal NLR cut-off value for new GC development at the time of eradication was 1.95 (sensitivity; 0.82, specificity; 0.65). Twelve patients died during the study period, and no treatment- or GC-related deaths were observed. A high NLR was associated with a significantly higher mortality rate (Hazard ratio [6.47], p=0.002).

Conclusion: High NLR was associated with *H. pylori* eradication failure using the VPZ regimen. A high NLR, history of GC, and history of hypertension were risk factors for new-onset GC within 5 years post-eradication, while a high NLR was also associated with a poor long-term prognosis after *H. pylori* eradication.

UNVEILING THE MECHANISM OF HELICOBACTER PYLORI IN GASTRIC CANCER IMMUNE EVASION THROUGH SPATIAL TRANSCRIPTOMICS OF PATHOLOGICAL SAMPLES

B. Chen¹, W. Kang²

Contact E-Mail Address: bonanchen@cuhk.edu.hk

Introduction: Gastric cancer remains a major health challenge globally, with *Helicobacter pylori* (*H. pylori*) infection being a well-known risk factor. Despite significant advances in understanding the pathological mechanisms of gastric cancer, the specific interactions between *H. pylori* and the host immune system within the tumor microenvironment are not fully elucidated. This study leverages cutting-edge spatial transcriptomic technologies to explore these interactions in gastric cancer samples.

Aims & Methods: This research aims to elucidate the mechanisms through which *H. pylori* contributes to immune evasion in the gastric cancer microenvironment. We utilized spatial transcriptomics on 71 gastric cancer samples, supplemented by single-cell transcriptomics on 10 of these samples to achieve a high-resolution view of cellular interactions. Advanced analytical techniques, including cell interaction networks, neighborhood analysis, and deconvolution mapping, were employed to dissect the complex interplay between tumor cells, immune cells, and *H. pylori*.

Results: Our results reveal a sophisticated mechanism by which *H. pylori* induces the recruitment and activation of cancer-associated fibroblasts (CAFs) and regulatory T cells (Tregs), facilitating an immunosuppressive tumor microenvironment. Spatial transcriptomics highlighted significant alterations in gene expression patterns conducive to immune evasion, primarily mediated by the interaction between *H. pylori*, CAFs, and Tregs. The integration of single-cell and spatial data provided a detailed map of the immune landscape, revealing key nodes and pathways involved in this process.

Conclusion: The findings of this study provide compelling evidence of *H. pylori*'s role in shaping the immune landscape of gastric cancer towards immunosuppression through the modulation of CAFs and Tregs. These insights underscore the potential benefits of immunotherapeutic strategies tailored for *H. pylori*-positive gastric cancer patients. Future therapeutic interventions could focus on targeting these specific interactions to enhance the efficacy of cancer immunotherapy in this cohort.

Disclosure: The authors declare no conflict of interest related to this study. Funding sources and affiliations have been reviewed to ensure no potential bias or influence on the research outcomes. All procedures followed were in accordance with ethical standards of the responsible committee on human experimentation and with the Helsinki Declaration of 1975, as revised in 2000.

EFFECTIVENESS OF IBD-BOOST, A DIGITAL COGNITIVE BEHAVIOURAL SELF-MANAGEMENT PROGRAMME FOR FATIGUE, AND/OR PAIN, AND/OR FAECAL INCONTINENCE IN INFLAMMATORY BOWEL DISEASE: MULTICENTRE RANDOMISED CONTROLLED TRIAL

R. Moss-Morris¹, C. Norton², A.L Hart³, F. Cleirigh Buttner⁴, T. Hamborg⁴, L. Miller⁴

Contact E-Mail Address: ailsa.hart@nhs.net

Introduction: Many people with IBD experience fatigue, pain and faecal incontinence (FI), impacting quality of life (QoL). We developed an interactive digital online self-management intervention (IBD-BOOST) based on a theoretically informed logic model and cognitive behavioural techniques.

Aims & Methods: To evaluate IBD-BOOST we conducted a multi-centre two-arm parallel group randomised controlled trial (RCT) comparing IBD-BOOST with Care as Usual (CAU), recruiting patients from clinics and national registries who rated the impact of fatigue and/or pain and/or FI as $\geq 5/10$. Those in the IBD-BOOST arm received 6 months access to the 12-session IBD-BOOST programme, a 30-minute telephone support call and weekly in-site email messages for 3 months. The UK Inflammatory Bowel Disease Questionnaire (UK-IBDQ) and global rating of symptom relief (GRSR) at 6 months were dual primary outcomes ($\alpha=0.025$ was considered statistically significant with two primary outcomes). Other secondary outcomes, including individual symptoms, were measured at 6 and 12 months. Complier-averaged causal effects (CACE), sensitivity and pre-specified subgroup analyses were conducted.

Results: 780 participants were randomised, 432 with Crohn's disease; 520 (66.7%) were female, mean age 49 years. At 6 months, both UK-IBDQ and GRSR were similar between the BOOST and CAU arms, $p=0.19$ for IBDQ and $p=0.39$ for GRSR. Adverse events were similar between groups. FI score and EQ5D utility score (secondary outcomes) were in favour of IBD-BOOST at 6 months, but pain and fatigue were no different. 57% of the intervention group completed a pre-defined minimum "dose" of 4 sessions (i.e. compliers). The CACE analysis suggested that compliers were more likely to report better QoL ($p=0.03$). Subgroup analysis of those meeting criteria for irritable bowel syndrome (IBS) at baseline, showed that IBD-BOOST was more effective in improving IBDQ and GRSR at 6 months when compared with CAU for the IBD-IBS group ($p_{\text{interaction}}=0.015$ and 0.046 , respectively).

Conclusion: This large RCT found that IBD-BOOST did not improve IBDQ and GRSR in patients with IBD and fatigue and/or pain and/or FI relative to CAU. Participants reported less FI at 6 and 12 months. Those with IBD-IBS improved more than those without.

Contact E-Mail Address: m.ghiboub@amsterdamumc.nl

Introduction: Fatigue represents one of the largest unmet clinical needs in inflammatory bowel disease (IBD), both during active and quiescent disease (1, 2). Tryptophan (Trp) metabolites play an important role in mediating mood regulation, intestinal homeostasis and immune responses (3, 4). Dietary Trp is metabolized in the intestines by three different pathways (i.e. kynurenine, serotonin and indole cascade). Previous studies have shown the importance of tryptophan/serotonin balance in fatigue and altered tryptophan serum levels have been reported in IBD patients (5, 6).

Aims & Methods: We aimed to explore changes in Trp metabolite plasma levels in fatigued IBD patients. In total, 40 IBD patients (22 Crohn's disease (CD) and 18 ulcerative colitis (UC) patients) in clinical and biochemical remission (21 females, HBI <5 , SCCAI ≤ 2 , CRP $<5\text{mg/l}$ and/or fecal calprotectin $<250\mu\text{g/g}$) and 25 patients (15 CD and 10 UC) with active disease (18 females; HBI >5 , SSCAI >2 , CRP $>5\text{mg/l}$ and/or fecal calprotectin $>250\mu\text{g/g}$) were included. Patients were classified as fatigued (and further classified as active vs remission: 17 vs 15 females, 6 vs 18 males) or non-fatigued (active vs remission: 1 vs 6 females, 1 vs 1 males) based on their Multi-dimensional Fatigue Inventory score (cut-off for fatigue: ≥ 40). Targeted quantitative analysis of 21 Trp metabolites was performed in plasma samples utilizing liquid chromatography coupled with quadrupole mass spectrometry. Receiving Operator Characteristic (ROC) curve and random forest analysis were used to assess the biomarker power of Trp metabolites for fatigue. Data were analyzed according to sex and fatigue status.

Results: 5-OH-Tryptophan (5-HTP) plasma concentrations, the direct precursor of serotonin, were significantly higher in fatigued compared to non-fatigued female IBD patients who were in remission ($p=0.02$), and this was not observed in male patients, independent of disease status nor in female patients with active disease. ROC analysis (area under the curve (AUC)=0.82) and Random Forest analysis showed that 5-HTP could distinguish between fatigue and no fatigue in females with quiescent IBD, as well as the 3-OH-Kynurenine/Indole-3-Aldehyde ratio (AUC=0.89).

Conclusion: 5-HTP might represent a novel biomarker for fatigue in female patients with quiescent IBD, but it should be acknowledged that the sample size of male patients and female patients with active disease was limited. The impaired balance between the kynurenine and serotonin pathway suggests a potential role for Trp metabolism in fatigued IBD patients. These results warrant a larger-scale, longitudinal study in male and female IBD patients, both with active and quiescent disease.

FATIGUE IN PATIENTS WITH INFLAMMATORY BOWEL DISEASES ASSOCIATES WITH ALTERED ANTIBODY RESPONSES AGAINST EPSTEIN-BARR VIRUS

M. Griesbaum¹, T. Vogl², M.C. Visschedijk¹, H. van Dullemen¹, E.A.M. Festen¹, G. Dijkstra¹, R.K. Weersma¹, A.R. Bourgonje¹

¹University of Groningen, Gastroenterology & Hepatology, Groningen, Netherlands, ²Medical university of Vienna, Center for Cancer Research, Vienna, Austria

Contact E-Mail Address: m.griesbaum@umcg.nl

Introduction: Patients with inflammatory bowel diseases (IBD) frequently experience fatigue, affecting up to 80% of those with active disease and approximately 50% with quiescent disease (1). The exact cause of IBD-associated fatigue is often unknown, making clinical management very challenging. Previous studies have suggested the potential involvement of infectious triggers and host immune responses in the development of fatigue.

Aims & Methods: In this study, we aimed to explore whether patients with quiescent IBD reporting fatigue exhibit specific systemic antibody responses, which could provide insight into potential immune reactivities underlying fatigue.

Systemic antibody epitope repertoires were profiled leveraging PhIP-Seq against 344,000 rationally selected peptide antigens. Fatigue severity was assessed on a 10-point Likert scale, ranging from 1 (no fatigue) to 10 (highest fatigue severity). Quiescent IBD was defined as clinical (Harvey-Bradshaw Index [HBI] <5 or Simple Clinical Colitis Activity Index [SCCAI] <2.5) and biochemical remission (C-reactive protein [CRP] <5 mg/L) at time of sampling. Multivariable logistic regression analyses, allowing adjustment for potential confounding factors e.g. age, sex, and smoking, were performed to identify associations between fatigue and systemic antibody responses.

Results: In total, 327 patients with IBD (156 with Crohn's disease [CD]; 171 ulcerative colitis [UC]) were profiled. A total of 153 different antibody-bound peptides were identified in association with fatigue considering nominal significance (nominal P-value <0.05), in the absence of significant associations after adjustment for multiple comparisons. Among antibodies nominally significantly associated with fatigue, 56 antibody-bound peptides (36.6%) were found in lower frequency among highly fatigued patients (fourth quartile, Q4), while 97 peptides (63.4%) were identified as more frequent in highly fatigued patients compared to those with lower fatigue scores (<Q4). Among highly fatigued patients, elevated antibody responses were primarily directed towards viral antigens, with by far the strongest signal against several antigens from Epstein-Barr virus (EBV), mostly directed at the EBV nuclear antigens 1 (EBNA-1) and 3B (EB-

NA-3B). In addition, elevated antibody responses were observed against bacterial antigens, including functional proteins from *Streptococcus* and *Staphylococcus* species. Most findings remained materially unchanged when we repeated analyses solely in patients with quiescent IBD, although antibody responses against EBV were altered, e.g. showing lower responses directed against the BLRF/BMRF/EA-D pathway. Furthermore, these antibody signatures were distinct from those recently identified in association with chronic fatigue syndrome (CFS) (2).

Conclusion: Fatigue in IBD is not reflected by distinct antibody epitope repertoires. However, our study suggests a potential involvement of viral antigens, particularly EBV, in IBD-associated fatigue. Although larger confirmatory studies are needed to validate these findings, this study shows that a technology like PhIP-Seq may represent a valuable strategy to approach the investigation of immune responses underlying complex symptoms such as fatigue.

Contact E-Mail Address: r.loveikyte@lumc.nl

Introduction: Lifestyle factors are significant contributors to fatigue, which affects approximately 45% of patients with Inflammatory Bowel Disease (IBD) in remission.

Aims & Methods: In this study, we evaluated the effect of a digital multimodal lifestyle intervention on fatigue in patients with IBD. Patients with IBD in biochemical remission (fecal calprotectin <150 mg/kg) were enrolled in a multicenter, non-randomized, controlled interventional study. The intervention group participated in a 12-month lifestyle program—provided by the non-profit organization Voeding Lefte—that included digital group meetings with a nutritionist and a lifestyle coach focusing on gradual and sustainable behavior change regarding nutrition, physical activity, sleep, and stress management. In addition, the program encouraged patients to exercise more self-control over their personal health. Following the initial six months, attendance at online sessions was not mandatory; however, patients could attend online sessions every six to 12 weeks to

stay motivated and foster the lifestyle habits they acquired throughout the course. Patients in the control group received standard care that included an informational leaflet about the potential causes of fatigue in IBD, the leaflet also included basic lifestyle information and advice to exercise more, eat a healthier diet, stop smoking, reduce alcohol intake, improve sleeping habits, and manage stress. The allocation to a study group was determined by the availability within the group and participant's ability to attend the scheduled intervention. Clinical data and patient-reported outcomes were collected. Fatigue was measured with the Functional Assessment of Chronic Illness Therapy-Fatigue (FACIT-F); any increase in FACIT-F after six months was considered a positive response to the intervention. The Minimal Clinically Important Difference (MCID) for fatigue was at least a four-point increase in the FACIT-F score¹. Inverse probability treatment weighting was used to correct confounding by indication.

Results: Thirty-six patients in the intervention group and 32 in the control group were compared. After six months, more patients in the intervention group (82.1% of patients) than in the control group (54.2% of patients) experienced improvement in fatigue, $P = 0.029$. Likewise, significantly more patients in the intervention group (71.4% of patients) than the control group (33.3% of patients) achieved a MCID regarding fatigue; $P = 0.006$. The improvements in fatigue were sustained throughout the study period in the intervention group. Acceptance of the health status was a significant factor for improvement in fatigue (β 7.813, SE 1.908, $P < 0.001$). Compared to the control group, quality of life improved in the intervention group; these patients gained 0.05 more quality-adjusted life years throughout the study. Last but not least, significant improvements in dietary quality were observed as early as three months after the baseline in the intervention but not the control group; these improvements in the intervention group were sustained throughout the study period.

Conclusion: Multimodal lifestyle intervention improves fatigue, quality of life, and dietary quality in patients with IBD who are in remission. Acceptance of the health status appears essential for fatigue improvement; instruments evaluating acceptance could help to personalize treatment and maximize its effectiveness.

USE OF THE INFLAMMATORY BOWEL DISEASE DISK AS A PSYCHOLOGY REFERRAL SCREENING TOOL

P. Girod¹, L. Harpur¹, L. Kumar¹, C. Coe¹, M. Hanly¹, M. Buckley¹, J. Sheridan¹, G. Cullen¹, G.A Doherty¹

¹St. Vincent's University Hospital, Gastroenterology, Dublin, Ireland

Contact E-Mail Address: parker.girod@gmail.com

Introduction: The Inflammatory Bowel Disease (IBD) disk is patient-led symptom scoring system for use during clinic visits to give physicians an overview of quality-of-life status in areas such as Emotion, Body Image, Sleep, Energy, Interpersonal Relations, Abdominal Pain, Education and Work, Sexual Function, Joint Pain, and Regulating Defecation.

The disk can be used to assess the need for psychological intervention in those with chronic diseases that exhibit high Emotion scores.

Aims & Methods: Assessing the performance of the IBD disk as a screening tool in a clinic setting for referrals to the IBD Psychology service.

A prospective initiative was introduced in which all patients were given an IBD disk at their clinic visit. Those with Emotion scores ≥ 7 were offered a referral to the IBD Psychology service.

Retrospective review was performed on all referrals to the IBD Psychology service over eight clinical weeks. Baseline demographics were collected such as age, sex, disease sub-type, surgical history, and disease activity at the time of clinic visit. Outcomes that were analysed included the number of patients who were willing to engage in the psychology service, reasoning for declining the service, and overall Emotion scores as reported on the disk.

Results: Over eight clinics, all patients were invited to fill out an IBD disk ($n=234$) and 29% of these patients ($n=69$) were offered a referral to the IBD Psychology service. The median age of referred patients was 43 years, 59% were female ($n=41$), 57% had Crohn's Disease ($n=39$), and 75% had no history of surgery ($n=52$). Of the referrals, 88% of patients were offered a psychology referral on the basis of high Emotion score on their IBD disk ($n=61/69$). The remaining patients ($n=8/69$) were referred following consultation with their physician.

46% of patients that were offered a referral, accepted it ($n=32$), with 75% ($n=24/32$) in the IBD disk cohort and 25% ($n=8/32$) in the other referral cohort. The patients that declined referral did so due to already engaging with external psychological support ($n=12$), personal reasons ($n=12$), or unknown reasons ($n=13$). The patients in the other referral cohort were offered referrals due to them enquiring about the psychology service ($n=2$) or from further prompting about their emotions from their physicians ($n=6$).

The median age of both IBD disk and non IBD disk cohorts was 43. The IBD disk cohort was 62% female ($n=38/61$) versus 38% female ($n=3/8$) in the other referral cohort. 54% of patients had a diagnosis of Crohn's Disease ($n=33/61$), 38% Ulcerative Colitis ($n=23/61$), and 8% IBD-Undiagnosed ($n=5/61$) versus 75% Crohn's Disease ($n=6/8$), 13% Ulcerative Colitis ($n=1/8$), and 13% IBD-U ($1/8$) in the IBD disk cohort and other referral cohort respectively.

Only 25% ($n=17/69$) patients that were referred had a history of IBD related surgery and 54% ($n=37/69$) of those referred were experiencing active disease during their clinic appointments.

Conclusion: The IBD disk is a helpful tool identifying patients for referrals to the IBD Psychology service for high emotional needs. Additional prompting from the treating physician during clinic appointments may identify more patients who would benefit from a psychology referral.

Introduction: Microscopic colitis (MC) is an inflammatory condition of the large intestine. Primarily diagnosed in middle-aged and older adults, the age-specific incidence of the disease peaks in patients 75-79 years of age. While MC is associated with a reduced quality of life, large-scale studies on the association with future psychiatric disorders are lacking.

Aims & Methods: Due to the burden of symptoms as well as inflammatory similarities between MC and certain psychiatric disorders, we hypothesized that patients with MC were at an increased risk of psychiatric disease. Using the nationwide histopathology cohort ESPRESSO, we identified 5,816 patients in Sweden with MC. These patients were matched, according to birth year, sex, and county, with reference individuals (n=21,509) from the general population. All individuals with previously recorded psychiatric disorders or dispensation of medication indicative of psychiatric morbidity were excluded. Our main outcome measure was a pre-devised collection of ICD-codes, all indicating psychiatric disease. Moreover, to control for the impact of intrafamilial confounding, full siblings to patients with MC were identified, and in a sensitivity analysis, used as reference population. Adjusted hazard ratios were computed using Cox proportional hazards modelling. Our main analysis included adjustments for the matching factors (birth year, county, sex) as well as educational attainment (as a proxy for socioeconomic status) and inflammatory bowel disease, celiac disease, and type 1 diabetes.

Results: From 2006-2021, 519 patients with MC and 1,313 reference individuals were diagnosed with psychiatric disorders (9.9 vs. 6.5 events per 1,000 person-years), corresponding to one extra case of psychiatric disorder in 29 patients with MC over 10 years. After adjustments, this represented a hazard ratio (HR) of 1.57 (95% confidence interval [CI]=1.42-1.74). We found significantly elevated estimates up to 10 years after MC diagnosis and similar HRs in lymphocytic and collagenous colitis. More specifically, we observed increased risks for unipolar depression, anxiety disorders, stress-related disorders, substance abuse, and suicide attempts in patients with MC.

Our result was robust across several sensitivity analyses (Table 1).

Conclusion: Patients with MC are at increased risk of incident psychiatric disorders compared to the general population. Specifically, this increased risk applies to unipolar depression, anxiety disorders, stress-related disorders, substance abuse, and suicide attempts. The increased risk was most pronounced among older patients with MC.

PATIENT-CENTERED THERAPEUTIC TARGETS IN INFLAMMATORY BOWEL DISEASE: A PERSONALIZED APPROACH TO IBD MANAGEMENT

H. Kallel¹, N. Elleuch¹, A. Hammami¹, A. Braham Ep Krifa¹, A. Ben Slama¹, H. Jaziri¹, M. Ksiai¹

Contact E-Mail Address: hamedkallel@hotmail.com

Introduction: Patients with Inflammatory Bowel Disease (IBD) encounter a wide range of symptoms, from the bowel and other non-specific symptoms. Physicians tend to focus on mucosal healing as a treatment target while little is known about issues important to patients. The aim of our study is to identify critical aspects of the daily burden impacting patients with IBD.

Aims & Methods: Ten dimensions of IBD-related disability were assessed in a cross-sectional survey, including patients followed and hospitalized between April and September 2023, using the self-administered IBD-Disk questionnaire. Patients were then required to select the three items they perceived as the main therapeutic goals and the three items they deemed least important. Disease clinical activity was assessed using Partial Mayo Clinic for Ulcerative colitis (UC) and Harvey Bradshaw Index for Crohn's disease (CD). Percentages were compared using the Chi-square test.

Results: We included 81 patients, 60.5% were male and 71.6% had CD. The mean age was 38.9 ± 12.6 and 59.3% were ≤ 40 at the time of inclusion. Life in urban areas was observed in 71.6% of the patients, a tertiary education in 40.7% and a high socio-economic level in 38.3% of the cases. The IBD was clinically active in 58% of the patients and 65.8% were on biotherapy. The items most frequently perceived as therapeutic goals were "Regulating defecation", "Abdominal pain" and "Energy" with a selection rate of 60.5%, 43.2% and 42.0% respectively. "Interpersonal interaction", "Sexual functions" and "Body image" were the most frequently selected items as least important disability dimensions with a 56.8%, 45.7% and 42.0% respective rate. Men and patients ≤ 40 tended to perceive "Education and work" as more important than women and patients > 40 (80.8% vs 19.2%, p=0.010, 84.6% vs 15.4%, p=0.001 respectively). CD patients tended to select "Abdominal pain" (82.9% vs 17.1%, p=0.050) and "Regulating defecation" (63.3% vs 36.7%, p=0.039) more frequently than UC patients as therapeutic goals. Furthermore, patients undergoing biotherapy were significantly more concerned about "Interpersonal interaction" than other patients (100% vs 0%, p=0.013). Patients living in urban areas appeared to perceive "Regulating defecation" as a main treatment target more frequently than patients living in rural areas (63.3% vs 36.7%, p=0.039). In addition, patients with active disease tended to prioritize "Sleep" more often than patients with clinical remission (81% vs 19%, p=0.013). In our study, tertiary education and high socio-economic level did not seem to significantly influence the treatment priorities to IBD patients.

Conclusion: The findings from this study would contribute to the understanding of the challenges faced by individuals living with IBD, offering valuable insights for physicians to prioritize areas of concern and narrow the perception gap between healthcare providers and patients. This increased understanding has the potential to alleviate the overall disease burden experienced by individuals with IBD.

Disclosure: Nothing to disclose.

Introduction: Therapeutic goals in inflammatory bowel disease (IBD) are constantly evolving and becoming increasingly ambitious. However, there are still unmet clinical needs. The concepts of response and remission through activity indexes are well established. Nevertheless, there is a wide range of clinical situations where they have not been standardized yet. Many patients show some degree of improvement, or partial response, but fail to meet defined objectives within the desired timeframe, leading to suboptimal therapeutic management. Therefore, early identification of partial responders is crucial for timely intervention, improving disease prognosis and quality of life.

Aims & Methods: Aim: To reach a consensus on the concept of partial response for different profiles of patients with IBD.

Methods: Initially, a scientific committee comprising 4 gastroenterologists and 2 hospital pharmacists involved in IBD management performed a literature review, defined the clinical scenarios and created the content of the Delphi questionnaire. Statements regarding partial response definitions in the short, medium, and long-term were defined for four different patient profiles: moderately-active ulcerative colitis (UC), acute severe UC; luminal and perianal Crohn's Disease (CD). A group of 60 IBD experts in Spain participated in this Delphi consultation. Panelists rated their agreement on a likert scale. Consensus was reached when at least 70% of panelists agreed or disagreed with a statement. Statements without consensus in the first round proceeded to subsequent iterative rounds until a consensus was met.

Results: Consensus was reached on 18 out of 22 statements in the first round and 4 in the second. The consensus definitions for partial response in different patient profiles are as follows:

1. Moderate UC (outpatient treatment):

- Short term: Clinical improvement without achieving clinical response.
- Medium term: Improvement without achieving clinical remission, with persistently elevated biomarkers (e.g. fecal calprotectin).
- Long term: Improvement without achieving clinical remission, with persistent inflammatory activity in biochemical parameters, imaging procedures, or endoscopic examinations.

2. Acute severe UC (admission):

- Short term: Clinical improvement without clinical response.
- Medium term: Clinical response.
- Long term: Improvement without achieving clinical remission, with persistent inflammatory activity in biochemical parameters, imaging procedures, or endoscopic examinations.

3. Luminal CD:

- Short term: Clinical improvement without achieving clinical response.
- Medium term: Clinical improvement without achieving clinical remission, with persistent inflammatory activity in biochemical tests.
- Long term: Clinical improvement without achieving clinical remission,

with persistent inflammatory activity in biochemical parameters, imaging procedures, or endoscopic examinations.

4. CD with perianal involvement:

- Short/medium term: Clinical improvement in the perianal area without clinical response.
- Long term: Clinical response of the perianal disease, with persistent inflammatory activity in imaging procedures or drainage of external openings.

Conclusion: Broad consensus was achieved on partial response definitions for various patient profiles in IBD. These standardized criteria can guide healthcare professionals in decision-making and assessing therapeutic effectiveness, ultimately improving patient care and outcome assessment.

Introduction: Therapeutic drug monitoring (TDM) of intravenous (IV) infliximab is increasingly practiced to improve therapeutic outcomes of patients with inflammatory bowel diseases (IBD). Recently, a subcutaneous (SC) formulation of infliximab was approved for maintenance treatment of IBD [1]. In the present work, we introduce a software tool to guide infliximab dosing by predicting infliximab concentrations after switching to the SC formulation.

Aims & Methods: The infliximab population pharmacokinetics (popPK) model was previously developed using data from pivotal trials [2]. The popPK model code was reconstructed using R (v4.3.0). A software tool was developed using the *Shiny* package (v1.7.4). Bayesian forecasting was implemented using *mapbayr* (v0.10.0), which was used to estimate individual PK parameters through maximum a posteriori estimation.

External validation data were obtained from the prospective, multicenter REMSWITCH trial [3]. For each patient, a pre-switch infliximab trough concentration (TC) was used to predict a post-switch TC. Predicted and observed post-switch TCs were compared, and absolute and relative prediction errors (PE) were calculated. Prediction errors were compared between patients with and without relapse. Relapse was defined as an increase in fecal calprotectin ≥ 150 mg/g from baseline.

A simulation study was performed to demonstrate how the software tool can guide the IV-to-SC switch. Simulation conditions were:

- Dosing: 10 mg/kg IV every four weeks (q4w) to 240 mg SC every two weeks (q2w)
- Patient: 70 kg, no antibodies towards infliximab (ATI), no co-administration of methotrexate
- Pre-switch TC: 17.6 mg/L

Results: A total of 77 patients contributed one pre/post-switch TC pair each. Three patients had detectable ATI in the pre-switch sample. Three other patients were cotreated with methotrexate.

Predicted infliximab TCs were unbiased in the absence of relapse (Table 1). However, the model tended to overpredict infliximab TC in patients who experienced a relapse.

	No relapse (N=60)		Relapse (N=17)	
	Median	[IQR]	Median	[IQR]
aPE (mg/L)	-0.06	[-2.4-3.3]	+3.8	[-1.0-5.7]
rPE (%)	-0.6	[-20.1-30.2]	+34.3	[-10.0-67.1]

Table 1. Predictive performance of the model.
Abbreviations: aPE, absolute prediction error (calculated as; predicted - observed); IQR, interquartile range; N, number of patients; rPE, relative prediction error (calculated as; [predicted - observed] / observed * 100%).

In the IV-to-SC simulation case, individual PK parameters (clearance 0.44 L/day, central volume of distribution 2.9 L, peripheral volume of distribution 27.0 L, and intercompartmental clearance 13.0 L/day) resulted in a post-switch TC of 18.6 mg/L right before the third SC injection. The simulation thus predicted no drop in TC after switching, thus presenting a likely safe switch strategy (considering the general belief that TCs drive efficacy).

Conclusion: The clinically validated, in-house developed software tool (<https://lpmx.shinyapps.io/infliximab/>) allows interactive simulations and personalized predictions to guide infliximab dosing while switching formulations. Predictions for patients without relapse were unbiased yet precision is likely compromised by variable SC bioavailability or possibly by time-varying PK. Overprediction of TC is likely driven by increased disease activity, characterized by an increased infliximab clearance and thus lower-than-expected infliximab observations, serving as a clinical alarm signal and warranting closer monitoring [4,5].

Introduction: The use of self-expandable metal stents (SEMS) as a bridge-to-surgery (BTS) for acute malignant large bowel obstruction has seen an increase in recent years, with high rates of technical and clinical success¹. However, the long-term oncological prognostic impact of colonic stenting has received mixed reviews in the literature, with concerns about lympho-vascular and perineural invasion at the tumour site, which could potentially lead to increased risk of metastatic recurrence and poorer long-term oncological outcomes.

Aims & Methods: We examined the risk of metastatic disease occurrence in a single tertiary centre in Singapore by performing an audit on outcomes over a 10-year period following SEMS insertion as BTS. Data of patients who underwent SEMS insertion for malignant bowel obstruction (MBO) between September 2013 – December 2023 were retrospectively reviewed. The occurrence of metastases on computed tomography (CT) scan was documented and the time to disease occurrence noted. Overall survival, metastases-free survival and occurrence of metastatic disease were analysed using Kaplan-Meier estimates.

Potential factors associated with metastatic occurrence, namely American Joint Committee on Cancer (AJCC) staging and completion of adjuvant chemotherapy, were analysed using Fisher’s exact test and Kaplan-Meier estimator respectively.

Results: A total of 132 patients underwent SEMS placement from September 2013 to December 2023 for MBO. We excluded 31 patients who had metastatic disease at diagnosis or who underwent colonic stenting for palliative decompression, and five who were lost to follow up. Of the 96 remaining patients who underwent colonic stenting as BTS, the mean age was 68.4 years and 47 (49.0%) were male. The median length of follow-up was 32 months.

Overall survival and disease-free survival were 90.9% and 66.2% respectively. Mean overall survival time was 86.8 months (95% CI [75.1-98.6]), mean metastases-free survival was 95.6 months (95% CI [88.7-102.5]). 24 patients (31%) developed distant metastases during the follow-up period. Median time to metastases was 14.1 months. Of these 24 patients, 20 (83.3%) were AJCC stage 3, and four patients (16.7%) were AJCC stage 2. In addition, 11 patients (45.8%) completed adjuvant chemotherapy; 13 patients (54.1%) declined adjuvant chemotherapy or had attenuated doses. Using Kaplan-Meier estimates, overall survival and occurrence of metastases were not found to be significantly associated with completion of adjuvant chemotherapy (P values of 0.056 and 0.114 respectively). Keeping in mind the relatively small sample size, these results need to be interpreted with caution. A positive association was found with higher AJCC staging and occurrence of metastases using Fisher analysis, with a P value of 0.037.

Conclusion: The rate of occurrence of distant metastases was similar to prior reported literature. The majority of patients who developed metastatic occurrence were AJCC stage 3 who declined or had attenuated adju-

vant chemotherapy. The data suggests that colonic stenting as BTS does not worsen long-term oncological outcome. Disease recurrence was related to disease stage and lack of effective adjuvant chemotherapy.

Introduction: The type of rectal cancer resection may impact oncological outcomes following total mesorectal excision. Non-restorative low anterior resection (NRLAR) may be performed in cases where anticipated functional outcomes are poor or technical challenges hinder anastomosis creation. Existing literature suggests that NRLAR may achieve inferior oncological outcomes compared to restorative low anterior resection (RLAR) and abdominoperineal resection (APR). Therefore, this study compared oncological and survival outcomes between NRLAR, RLAR, and APR at three years postoperatively.

Aims & Methods: This retrospective cohort study encompasses all elective NRLAR, RLAR, and APR procedures performed for non-metastatic primary rectal carcinoma across 11 Dutch centers between 2013 and 2020. The primary outcome measured was 3-year disease-free survival (DFS), while secondary outcomes included 3-year overall survival (OS) and local recurrence (LR). Data analysis employed Kaplan-Meier survival analysis, and results were juxtaposed using log-rank testing. The association between resection type (NRLAR, RLAR, and APR) was further explored using multivariate Cox regression analysis.

Results: A total of 2069 patients were analysed, with 258 (12.5%) undergoing NRLAR, 1153 (55.7%) RLAR, and 658 (31.8%) APR. NRLAR demonstrated a lower three-year DFS at 70.8%, compared to RLAR (82.3%) and APR (77.5%) ($p < 0.001$). Similarly, three-year OS and LR were inferior for NRLAR (82.4%) in contrast to RLAR (93.5%) and APR (90.2%) ($p < 0.001$), and 7.9% (NRLAR) versus 3.2% (RLAR) and 4.5% (APR) ($p = 0.003$), respectively. Multivariate Cox regression analysis revealed NRLAR to be independently associated with worse DFS (HR 1.353; 95% CI: 1.061 – 1.803; $p = 0.039$), OS (HR 1.594; 95% CI: 1.065 – 2.386, $p = 0.023$), and a higher LR risk (HR 2.879; 95% CI: 1.667 – 4.975; $p = < 0.001$).

Conclusion: NRLAR is independently correlated with unfavourable oncological and survival outcomes when compared to RLAR and APR.

Introduction: It is widely acknowledged that postoperative complications after colon cancer resection are associated with postoperative mortality, but the association with long-term outcomes is controversial. This study examined the impact of postoperative complications on locoregional recurrence, defined as any intra-abdominal recurrence including peritoneal metastases, and overall survival.

Aims & Methods: This national, population-based cross-sectional cohort study was carried out in 46 Dutch hospitals. Patients who underwent colon cancer resection between January 2014 and December 2015 were eligible. Long-term outcomes were assessed in patients without synchronous metastases and a minimum follow-up of 6 months using logistic regression, Kaplan-Meier, log-rank test, and Cox regression analyses.

Results: A total of 8936 patients were included with a median follow-up of 59.6 months (IQR 28.0-65.6). Any complication occurred in 2649 (29.6%) patients, of whom 1576 had surgical complications (806 requiring re-intervention) and 1791 non-surgical complications. When looking into patients with stage 1 to 3 colon cancer with a minimum follow-up time of 6 months, 7.5% of the cohort without any complication versus 9.2% with a complication develop a locoregional recurrence ($p=0.023$). Independent risk factors for locoregional recurrence were surgical approach, emergency setting, tumour location, pT, pN and resection margin status. Five-year overall survival probability was 86.7% versus 76.1% for patients with or without complications respectively ($p<0.001$), which remained significant in multivariable analysis (HR 1.43, 95CI% 1.29-1.59).

Conclusion: This study showed worse overall survival after a complicated postoperative course in stage I-III colon cancer patients, but no independent association with locoregional recurrence was found.

Disclosure: Nothing to disclose.

Introduction: Endoscopic submucosal dissection (ESD) is increasingly employed for colorectal endoscopic resection (ER) in specialist units around the world. Abundant Japanese series and more recent western

series report the outcomes of ESD, invariably reporting en bloc resection and R0 resection rates as a quality reporting measure. Whilst en bloc resection is well established to result in very low levels of recurrent/residual adenoma, evidence for recommending R0 resection is lacking. Furthermore, determining R0 status is subject to variations in specimen processing and histopathological examination.

Aims & Methods: We aimed to determine the significance of histopathological R0 resection on residual/recurrent adenoma at 6 month surveillance. Patients with LNCP treated by ESD with en bloc resection at a tertiary referral centre between September 2011 and September 2023 and who had completed the first surveillance at 6 months (SC1) were included. During surveillance the scar from ER was identified and examined with magnification chromoendoscopy and NBI/BLI. Only abnormal scars were biopsy sampled.

The incidence of recurrent/residual adenoma at 6 months in patients who had confirmed histopathological R0 resection was compared with patients who did not have confirmed R0 resection.

Results: 1400 LNCP underwent an initial successful ER over the study period, 665 by ESD and 735 by EMR/pEMR. 796 LNCP were resected en bloc and were included for analysis. Of these, Histopathological R0 resection was confirmed in 690 (86.9%). The mean lesion size was 44.5mm +/-25.6 mm (median 38.5mm, range 20mm-210mm). 518 patients had undergone SC1. Only 4 patients had residual/recurrent adenoma (0.77%). Only 1 patient who did not have confirmed R0 resection experienced recurrence and there was no association between confirmed R0 resection and recurrence (OR 0.41, 95% CI 0.04-4.02, p=0.41).

Conclusion: Histopathological R0 resection has no impact on outcome. In the colorectum, the margins of LNCP are readily apparent and complete resection is straightforward to confirm during ESD. Therefore, if high quality ESD is performed by experienced practitioners, in many cases lack of confirmation of R0 resection is likely to be a result of the difficulties in histopathological interpretation of often very large specimens. Recurrent/residual adenoma rates at surveillance would be a better quality metric for ESD along with en bloc resection rate.

Introduction: Organ preservation using local resection techniques for early colon cancer (CC) is receiving increasing attention. However, there is a significant difference in the primary treatment approach between pT1 and pT2 CC.

Aims & Methods: The objective of this study was to assess whether the depth of tumor invasion (T-stage) correlates with the survival and recurrence rates among patients who underwent surgical treatment for T1 and T2 CC. A multicenter retrospective cohort study was conducted, including patients who underwent curative surgery for T1 or T2 CC between 2014 and 2015. Patients in this cohort were originally identified through the Dutch ColoRectal Audit (DCRA), a prospective national registry of all patients undergoing surgery for primary colorectal cancer. Long-term oncological follow-up data from the original patient records were added to the DCRA data by surgical residents affiliated with the DSRG from 61 participating hospitals. The primary outcome measures were 5-year overall and distant metastasis-free survival (OS/MFS). Survival outcomes were compared with the Kaplan-Meier method and log-rank test. Cox proportional hazard models were used to analyze risk factors associated with these outcomes.

Results: In total, 928 patients with pT1 CC and 1349 patients with pT2 CC were included. Lymph node metastases (LNMs) were identified in the resection specimen in 118 (12.7%) out of 928 patients in the pT1 cohort and in 252 (18.7%) out of 1349 patients in the pT2 cohort. Locoregional recurrences occurred in 3 (0.3%) of patients in the pT1 cohort and 20 (1.5%) of patients in the pT2 cohort (P = 0.07). Distant metastases were observed in 30 (3.2%) out of 928 pT1 patients and in 66 (4.9%) out of 1349 pT2 patients (P = 0.05). Most patients who developed distant metastases during follow-up initially had no LNMs and were therefore staged as N0. Specifically, in the pT1 cohort, 20 out of 30 patients (66.6%) with distant metastases were initially staged as pT1N0, while in the pT2 cohort, 38 out of 66 patients (57.6%) were staged as pT2N0. The 5-year OS did not differ between the pT1N0 and pT2N0 patients (85.2% vs. 86.9%, p = 0.49, multivariable HR for pT2 adjusted for age, gender, ASA score and tumor location; 0.8, 95% CI 0.57 - 1.009), and neither did the 5-year MFS (96.0% vs. 95.9%, p = 0.65, multivariable HR 1.2, 95% CI 0.7 - 2.0). For patients with pT1N+ and pT2N+ stage, 5-year OS was 83.5% vs. 81.6% (p = 0.59, multivariable HR adjusted for administration of adjuvant chemotherapy of 1.0, 95% CI 0.6 - 1.8) and MFS was 90.9% vs. 87.1% (p = 0.43, multivariable HR adjusted for pN-stage and administration of adjuvant chemotherapy of 0.8, 95% CI 0.6 - 1.2).

	T1 N0 n = 810	T2 N0 n = 1097	p value	T1 N+ n = 118	T2 N+ n = 252	p value
Recurrent disease, n (%)	22 (2.7)	43 (3.9)	0.15	11 (9.3)	34 (13.5)	0.25
Loco regional recurrence only	2 (0.2)	5 (0.5)		1 (0.8)	5 (2)	
Distant metastases only	19 (2.3)	34 (3.1)		8 (6.8)	24 (9.5)	
Loco regional recurrence + distant metastases	1 (0.1)	4 (0.4)		2 (1.7)	5 (2)	
5-Year Overall Survival	85.2%	86.4%	0.49	83.5%	81.6%	0.59
5-Year Metastasis free survival	96.0%	95.9%	0.65	90.9%	87.1%	0.43

Conclusion: In early colon cancer, the depth of tumor invasion (pT1 or pT2) does not significantly affect the patient's metastasis-free or overall survival after oncological resection. In both cohorts (pT1 and pT2), the majority of distant metastases arise in patients without LNMs at the initial time of surgery (N0). Therefore, it could be questioned whether segmental colon resection with lymph node dissection is of oncological and clinical benefit in all cases.

Disclosure: Nothing to disclose.

Introduction: It has been suggested that the development of cancer chemotherapy resistance may result from the intricate interplay between gene regulation and external environmental factors. Immune biomarkers hold promise as prognostic indicators for the efficacy of chemoradiotherapy; nevertheless, to date, none have been successfully achieved in routine clinical practice.
Aims & Methods: This study is a sub-analysis of data from the prospective IMMUNOREACT 2 trial (NCT04917263) including all the patients who underwent adjuvant therapy. Healthy rectal mucosa adjacent to the cancer was collected during surgery. Gene expression profiling was performed with Nanostring technology using nCounter® PanCancer IO 360™ Panel. Prospectively collected rectal mucosa samples were subjected to flow cytometry to determine the proportion of epithelial cells (Cyt-20+) acting as antigen-presenting cells (expressing CD80, CD86, HLAABC), activated T cells (expressing CD25, CD28, CD38), regulatory T cells (CD4+CD25+FoxP3+) or exhausted T cells (CTLA-4+). Non-parametric tests were used for small sample size comparisons. This study aims to evaluate immune biomarkers' role in determining adjuvant therapy's effectiveness in rectal cancer (RC) patients.
Results: A total of 31 patients with RC who underwent adjuvant therapy included in the prospective IMMUNOREACT 2 cohort were analyzed; during a median follow-up time of 20.8 months, 7 patients experienced relapse. Preliminary gene expression analysis on 19 specimens revealed 25 differentially expressed genes between patients who relapsed (n=3) and those who did not (n=16) (Fig. 1 A, B). In particular, in the normal rectal mucosa of patients who relapsed, downregulation of genes associated with macrophages (CD163, CEBPB, MARCO, MS4A2, MS4A4A, MS4A6A, SIGLEC1), inflammation (CCL8, C5, C5AR1, IL11RA, TIE1) and lymphocytes stimulation (VTCN1, TNFSF13B) was observed. Relapse was associated with a high CD8+ CD28+ cytotoxic lymphocytes mean fluorescence intensity (MFI) (p= 0.05). The accuracy of predicting relapse was AUC=0.765 for CD8+CD28+ MFI (Fig. 2 A, B).
Conclusion: Our preliminary data suggest that the immune-related markers signature in the healthy peritumoral mucosa might be useful for predicting relapse after adjuvant therapy in rectal cancer patients. Moreover, relapsing patients showed lower stimulation of macrophages and lymphocytes, thus suggesting that impaired immune surveillance might influence adjuvant therapy outcomes. Sampling healthy mucosa might help the decision-making about adjuvant therapy after surgery for rectal cancer.

COMPARISON OF THE PROGNOSIS AND LYMPH NODE METASTASIS BETWEEN “NO TUMOR BUDDING” AND “LOW-GRADE TUMOR BUDDING” IN T1 AND T2 COLORECTAL CANCER

J.Y. Lee¹
¹Dong-A university, Gastroenterology, Busan, Republic of Korea, South Korea

Contact E-Mail Address: ljyhateo@gmail.com
Introduction: Tumor budding is a significant prognostic value in the management of colorectal cancer (CRC). There are grades of tumor budding: 0-4 buds as low, 5-9 buds as intermediate, and more than 10 buds as high. However, the specific prognosis difference between cases with 0 buds and those with 1-4 buds, is not well-established due to a lack of comparative studies.
Aims & Methods: The aim of this study is to examine and compare the rate of lymph node (LN) metastasis and prognosis by distinguishing between 0 buds and 1-4 buds within the low-grade category (0-4 buds) of tumor budding in T1 and T2 CRC. This study retrospectively identified a total of 224 cases of T1 and T2 CRC from 2015 to 2018 across three medical institutions using medical records. The pathology, including the assessment of tumor budding, was subsequently reconfirmed, and the recurrence and survival of patients were evaluated up to December 2023.
Results: Patients in the BD1 group exhibited a higher T stage compared to BD0, accompanied by significantly increased rates of lymphovascular invasion and perineural invasion. The prevalence of LN metastasis was 14.8%. No significant difference in LN metastasis was observed between BD0 and BD1. In a multivariate analysis exploring factors associated with LN metastasis, relevant factors included lymphatic invasion, perineural invasion, and 5 buds or more. (Table 1) There were no significant distinctions in 5-year survival and progression free survival rate between the BD0 and BD1 groups (P=0.971).

	Univariate analysis		Multivariate analysis	
	OR	P-value	OR	P-value
Lymphatic		0.000		0.025
Lv 0: Lv 1	1:10.557 (4.188-26.712)		1:3.843 (1.181-12.510)	
Perineural		0.000		0.000
Pn 0: Pn 1	1:31.167(8.073-120.328)		1: 35.774 (6.655-192.317)

Introduction: Colorectal cancer (CRC) patients commonly encounter anemia, with estimates indicating that up to 58% are affected and iron deficiency (ID) anemia being the most prevalent. This study aimed to compare the efficacy and safety of preoperative intravenous iron (IVI) with standard care (no iron or oral iron) in CRC patients with ID anemia.

Aims & Methods: We conducted a systematic search of the Cochrane Library, PubMed, Scopus, and Web of Science databases from inception to September 20, 2023, to identify studies comparing intravenous iron (IVI) versus standard care in colorectal cancer (CRC) patients with iron deficiency anemia. Pooled results were analyzed for changes in hemoglobin (Hb) levels from baseline, need for red blood cell (RBC) transfusions, mean number of RBC units transfused, overall survival (OS), disease-free survival (DFS), and complications. We evaluated randomized clinical trials using the Cochrane Risk of Bias 2 tool and observational studies using the Newcastle Ottawa Scale. Statistical analysis was performed using Revman software Version 5.4.1.

Results: We analyzed data from 11 studies, encompassing 2,024 patients, and found that IVI significantly increased Hb levels at various crucial time points: preoperative (MD=1.17, CI 95% [0.95, 1.40], P<0.01), postoperative day one (MD=1.32, CI 95% [0.89, 1.76], P<0.01), hospital discharge (MD=0.76, CI 95% [0.28, 1.24], P=0.002), and 30 days postoperative (MD=1.57, CI 95% [1.27, 1.87], P<0.01). The overall need for RBCT significantly decreased with IVI (RR=0.39, CI 95% [0.27, 0.56], P<0.01), particularly in the postoperative period (RR=0.69, CI 95% [0.52, 0.92], P=0.01). No significant differences were found between preoperative and intraoperative periods. IVI notably reduced transfused red blood cell units, total complications, and wound dehiscence. However, there were no significant differences in total death, hospital stay, OS and DFS.

Conclusion: Preoperative IVI significantly increased Hb levels at critical time points and markedly reduced the overall need for RBCT, complications, and wound dehiscence. To further validate these findings, more well-designed randomized controlled trials are warranted.

Disclosure: Nothing to disclose.

EVALUATING THE INCREMENTAL PREDICTIVE VALUE OF THREE FECAL HEMOGLOBIN CONCENTRATIONS COMPARED TO TWO FOR FUTURE PREDICTION OF COLORECTAL CANCER

L. Mwangi¹, A. Katsara¹, I. Lansdorp-Vogelaar¹

¹Erasmus MC University Medical Center, Public Health, Rotterdam, Netherlands

Contact E-Mail Address: l.mwangi@erasmusmc.nl

Introduction: The fecal immunochemical test (FIT), utilized for fecal hemoglobin (f-HB) detection in stool, stands as a recommended screening approach for colorectal cancer (CRC) (1). Prior research has shown the predictive ability of f-HB concentration over two previous screening rounds in predicting future risk of CRC (2). However, there remains a gap in literature on the additional benefit of incorporating more than two f-HB concentrations.

Aims & Methods: In this study, we aim to assess the added prognostic value of using three preceding rounds of f-HB concentrations compared to using two rounds in risk prediction of Advanced Neoplasia (AN) and CRC. In our analysis, we utilize data from the fourth round of the Dutch CRC screening program. We first develop a prognostic model for detecting AN and CRC, incorporating participants age, sex, and f-HB concentrations from rounds 1, 2, and 3 as predictor variables. Similarly, we develop a separate model using only f-HB concentrations from rounds 2 and 3, along with sex and age as predictors. Model performance is assessed using receiver operating curve (AUC) and visual calibration inspection. We further report on the net classification improvement (NRI) and integrated discrimination improvement (IDI) to quantify how the models with 3 rounds of f-HB levels enhance the reclassification of participants with and without AN or CRC. Positive values of both NRI and IDI with a p-value of <0.005 indicate a significant improvement in classification of participants.

Results: Among study participants, 56959 (4.7%) had a positive FIT result, 15170 (1.2%) had AN detected and 2465 (0.2%) had CRC. The model with three rounds of f-HB levels outperformed the model with two rounds in discriminating patients with AN and CRC. Specifically, AUCs for AN and CRC were 0.76 (95% CI, 0.75-0.77) and 0.73 (95% CI, 0.66-0.74) respectively for model with three rounds of f-HB levels. Both NRI and IDI were positive with p values of <0.005 indicating an improvement in classification of participants with and without AN and CRC when using three rounds of f-HB concentrations compared to using two rounds.

	Outcome	AUC model with age, sex f-HB levels 1, 2 & 3 rounds (95%CI)	AUC model with age, sex f-HB levels 2 & 3 rounds (95%CI)
Training data	AN	0.76 (0.75 - 0.77)	0.73(0.72- 0.74)
	CRC	0.73(0.70 - 0.74)	0.71 (0.69- 0.72)
Validation data	AN	0.76 (0.75 - 0.77)	0.73(0.72- 0.74)
	CRC	0.73 (0.66 - 0.74)	0.69 (0.66 - 0.71)

Table 1: Values for AUC for models with three and two rounds of f-HB levels with age and sex as predictor variables for risk of AN and CRC

Abbreviations: AUC, area under the curve; CI, confidence interval;

AN, advanced neoplasia; CRC, colorectal cancer; f-HB, Fecal Hemoglobin

Conclusion: Our findings suggest that the model integrating three f-HB levels surpasses the two-level model in discrimination and reclassification. Therefore, using more preceding rounds of f-HB concentrations could potentially enhance personalized screening of CRC within the Dutch screening program.

Introduction: Computer-aided detection (CAdE) system increases the efficiency of adenoma detection during colonoscopy, which is expected to reduce the incidence of colorectal cancer as well as cancer treatment-associated medical costs. However, most lesions detected using CAdE have been reported to be diminutive adenomas that may not affect patient prognosis. Additionally, CAdE may impose an immediate economic burden because the system needs to be purchased. Consequently, the use of CAdE for all colonoscopy procedures seems impractical. This study aimed to evaluate the usefulness of CAdE in patients undergoing regular surveillance colonoscopy (SCS), to identify the characteristics of endoscopists and patients who may benefit significantly from CAdE.

Aims & Methods: Patients who underwent regular SCS with CAdE at Hiroshima University Hospital from January to March 2023 and had undergone colonoscopy at least twice in the previous three years using a conventional detection method were enrolled. Forty-eight endoscopists who had collectively performed ≥ 800 colonoscopies performed the examinations. Endoscopic resection was performed for lesions ≥ 6 mm in size, flat and depressed neoplastic lesions ≤ 5 mm in size, and lesions with suspected high-grade dysplasia or T1a carcinoma, according to Japanese guidelines. Diminutive polypoid adenomas ≤ 5 mm in size were followed up without resection. Lesions pathologically identified as adenomas > 6 mm or carcinomas were defined as index lesions (ILs). Lesions pathologically identified as adenomas ≥ 10 mm in size, tubulovillous adenomas, and high-grade dysplasia were defined as advanced adenomas (AAs). The clinicopathological findings of the lesions detected by CAdE were evaluated, and the outcomes were compared between the semi-clean colon (diminutive polypoid adenomas ≤ 5 mm in size followed up without resection) and clean colon (no adenomatous polyps) groups.

Results: Overall, 78 patients were included. CAdE identified 46 adenomas that were not detected by previous colonoscopy in 28 patients, including three ILs but no AAs. The mean withdrawal time was 824 ± 353 s, and the mean tumor diameter was 3.3 mm (range, 2–8 mm). The most common gross type was 0-Is (70%), followed by 0-Isp (17%) and 0-IIa (13%). Most tumors were located in the ascending and sigmoid colons (28%), followed by the transverse colon (26%), cecum (7%), descending colon (7%), and rectum (4%). The ILs were 0-Isp of 6 mm diameter in the ascending colon, 0-Is of 7 mm diameter in the transverse colon, and 0-Isp of 6 mm diameter in the descending colon, all of which were adenomas with lesions on the folds. Overall, 34.1% and 38.2% of the patients in the semi-clean and clean colon groups, respectively, had newly detected adenomas. No new neoplastic lesions were detected using CAdE in patients without a history of endoscopic resection. When comparing the clinical backgrounds of patients with and without new ILs detected in CAdE SCS, a significant difference was found in the IL detection rate at the previous SCS between the groups (67% vs. 12%, $p = 0.0319$).

Conclusion: CAdE may help detect adenoma in SCS for patients with semi-clean colons and those with clean colons and a history of endoscopic resection. Its effectiveness is considered more for patients with ILs at the previous SCS.

PREVALENCE AND RISK FACTORS OF METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE IN KOREAN AIR FORCE ARMY INCLUSIVE OF PILOTS: 2020-2022

D.H. Song¹, B. Ku²

¹Korean Air Force Aerospace medical center in South Korea, Department of Internal Medicine, Cheongju-si, South Korea, ²Korea Institute of Oriental Medicine, Daejeon-si, South Korea

Contact E-Mail Address: engus1026@gmail.com

Introduction: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a disease that complements Nonalcoholic Fatty Liver Disease (NAFLD) and is newly defined in 2020. It is defined based on metabolic abnormalities, regardless of the presence of liver disease caused by other causes such as alcohol consumption. Regarding the newly defined MAFLD, there has not been many studies related to the prevalence and risk factors in Korea, and no studies were found targeting soldiers, especially pilots.

Aims & Methods: The purpose of this study is to identify prevalence and risk factors for MAFLD in Korean air force army inclusive of pilots. The subjects are 1044 soldiers who underwent health checkups in Korean Air Force Aerospace medical center from January 2020 to December 2022. The data was retrospectively collected including age, height, weight, body mass index, waist circumference, blood pressure, smoking, drinking, exercise intensity, various blood test results, presence of fatty liver, and degree of fatty liver. Risk factors were analyzed using logistic regression.

Results: There were 667 pilots (64%) in our study, of whom 477 (72%) were high-performing pilots. The prevalence of MAFLD was 316 (30%) in all soldier. There was difference in the prevalence of MAFLD between pilot and non-pilot group (pilot group: 185 (28%), non-pilot group: 131 (35%) p -value=0.018). According to the multivariate analysis, body mass index (BMI), diabetes, systolic blood pressure, triglycerides (TG), uric acid (UA), high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), alanine aminotransferase (ALT) were a risk factor associated with MAFLD among the entire soldiers. When categorized into pilot and non-pilot group, risk factors were associated with BMI, diabetes, alcohol consumption, and ALT in the non-pilot group. In the pilot group, they were statistically associated with age, BMI, dyslipidemia, TG, UA, HDL and ALT. Among them, UA showed the largest difference between the non-pilot group and the test group (non-pilot group: 1.14 (95% CI: 0.80-1.62), pilot group: 1.80 (95% CI: 1.38-2.36)).

Conclusion: There was a difference in the prevalence of MAFLD between pilot and non-pilot group. In particular, UA could be used to predict MAFLD as a specific risk factor in pilots comparing with non-pilots.

Disclosure: Nothing to disclose.

LIVER STEATOSIS: A RISK FACTOR FOR THE DEVELOPMENT OF COLONIC ADENOMAS?

R. Abbas¹, E. Mikhael¹, M. Khanfour¹, S. Helou¹, L. Amer¹, K. Honein¹, R. Slim Karam¹, E. Mahfouz¹, J. Amara¹, C. Yaghi¹

¹Université Saint-Joseph, Beirut, Lebanon

Contact E-Mail Address: eliomikhael7@gmail.com

Introduction: Several studies have suggested a possible association between hepatic steatosis and colonic adenomas, positioning hepatic steatosis on the list of potential risk factors.

Aims & Methods: Our study aims to investigate the relationship between hepatic steatosis and the development of colonic adenomas. This is an observational study, with both a retrospective and a prospective arm, spanning from 2017 till 2023. Selected patients are those who underwent a Fibroscan and a colonoscopy during the same year. We collected demographic data, medical history, medication intake, and results of both Fibroscan and colonoscopy. Our population was divided in two: population A with a Controlled Attenuation Parameter (CAP)<258 and population B with a CAP³≥258. The main outcome was the presence of adenomas on colonoscopy.

Results: In total, our analysis included 232 patients. A ROC curve was obtained, determining that a CAP³≥258 was associated with the presence of adenomas on a colonoscopy with an AUC of 0.630 with a sensitivity and specificity of 65% and 64% respectively. From these 232, 125 patients had a CAP³≥258 (53.8%) and 107 patients had a CAP<258 (46.2%). Patients with a CAP³≥258 more frequently exhibited: hypertension (54% vs 35.7%, p=0.016), diabetes (36% vs 10.7%, p<0.001), and dyslipidemia (70.6% vs 29.8%, p<0.001) compared to those with a CAP<258. The BMI was higher (29.2 vs 26.7, p=0.001) in the group (CAP³≥258). Finally, adenomas were more frequent (46.4% vs 33.6%, p=0.025) in this same group.

A multivariate analysis was done. The presence of CAP³≥258 (OR 2.58, p=0.017), diabetes (OR=3.71, p=0.02), and older age (OR=1.04, p=0.017) are associated with the presence of adenomas on colonoscopy.

Conclusion: Hepatic steatosis is independently associated with the presence of adenomas with an OR of 2.58. Therefore, early screening for colorectal cancer might be warranted in patients with hepatic steatosis. Further studies are required to establish hepatic steatosis as a risk factor of colonic adenomas.

Disclosure: Nothing to disclose.

Contact E-Mail Address: pavlenko.nat.v@gmail.com

Introduction: It is known that one of the markers of metabolically associated fatty liver disease is disruption of the intestinal microbiota and changes in intestinal permeability with the development of increased epithelial permeability syndrome. All this leads to the translocation of endotoxins, liposaccharides, harmful bacteria and reactive oxygen species from the intestinal lumen into the circulation, where they are absorbed by the liver, which can cause increased lipogenesis and inflammation, which in turn can provoke the development of MASLD and leads to its progression.

Aims & Methods: Aims: to study the features of clinical manifestations, physical development and disorders of the intestinal microbiota in children with MASLD.

Methods: 147 children with MASLD aged 6-18 years were observed. The diagnosis was verified based on the criteria of the EASL 2023 recommendations (markers of cholestasis, lipid profile, ultrasound of the liver and gallbladder), and the results of bacteriological examination of stool were assessed.

Results: The predominant complaints (in 87% of patients) were: increased fatigue, irritability, emotional lability, discomfort in the right hypochondrium not related to food intake; In 65%, slight hepatomegaly was detected by palpation. 18 children were overweight: 8 children were at risk of obesity (BMI – 25.0 – 29.9); 7 children with grade I obesity (BMI – 30.0 – 34.9); 3 children with second degree obesity (BMI – 35.0 – 39.9). 4 children had type I diabetes mellitus, 12 had type II diabetes mellitus, and 15 had impaired glucose tolerance. Symptoms of arterial hypertension were detected in 23 children. A biochemical study revealed an increase in markers of cholestasis in almost all children (141 out of 147): alkaline phosphatase and gamma-glutamyltranspeptidase; 22 children had cytolytic syndrome of moderate activity (2-3 norms) due to ALT, 59 had dyslipidemia due to cholesterol and triglyceride fractions; 31 children had hyperglycemia. All children underwent studies of markers of viral hepatitis, levels of transferrin, ferritin, ceruloplasmin, a-1-antitrypsin, ANA, AMA, SMA, LKM-1, which made it possible to exclude viral hepatitis, hemochromatosis, Wilson's disease, and a-1-antitrypsin deficiency, autoimmune liver diseases. During ultrasound examination, there was a phenomenon of attenuation of the ultrasonic wave, an increase in the brightness of the parenchyma and a deterioration in the visualization of the vessels and bile ducts of the liver.

When assessing the intestinal microbiota, a decrease (in 65%) of Bifidobacterium, Bacteroids, Lactobacillus and an increase in opportunistic bacteria were revealed: Enterobacteriaceae, Proteobacteria (Escherichia), Parabacteroids, Ruminococcaceae, Fusobacterium (impaired intestinal microbiocenosis degree I-II).

Conclusion: In the majority of children (87%) with MASLD, nonspecific complaints of general asthenia, minor hepatomegaly (65%) prevailed, a third had excess body weight, and occasionally (9.5%) impaired glucose tolerance. 96% of children have increased biochemical markers of cholestasis. Disturbances of the intestinal microbiota are often found in children with MAFLD; they can both provoke the development of MASLD and support the inflammatory process in the liver; they require adequate correction.

Disclosure: no conflict of interest.

PREDICTORS FOR MAJOR CARDIOVASCULAR EVENTS OR LIVER RELATED EVENTS IN LIVER BIOPSY PROVEN MASLD PATIENTS: A LONG-TERM FOLLOW-UP COHORT

S. Treeprasertsuk¹, P. Ananchuensook¹, K. Thanapirom¹, C. Phathong¹

¹Chulalongkorn University, Medicine, Patumwan, Thailand

Contact E-Mail Address: battan5410@gmail.com

Introduction: MASLD patients is increasing worldwide and the clinical outcomes of different phenotypes had shown varied especially the occurrence of liver related events (LRE) or major cardiovascular events (MACE) (Eslam M, et al. Hepato Inter 2020, 14:889–919). In addition, the prognostic factors for LRE, or MACE, are not well studied.

Aims & Methods: Aims: We aimed to study the rate of LRE, or MACE and the predictors for LRE, or MACE, in MASLD patients with liver biopsy proven.

Methods: In a single-tertiary-center prospective cohort, we collected data of MASLD patients with biopsy-proven who were followed up of at least 1 years at King Chulalongkorn Memorial Hospital during 2005-2022. The primary outcome was the presence of LRE. or MACE. which included cirrhotic complications: acute decompensations; EV/GV bleeding, ascites, hepatic encephalopathy or HCC or acute complications requiring liver transplantation or death. MACE was defined by the occurrence of stroke or acute coronary disease or myocardial infarction. Related baseline characteristics, LSM, FIB-4, and liver biopsy were collected.

Results: Among 286 MASLD patients, the MASLD patients with mean age of 50.1 +/- 14.5 years old (range 19-80 yr.) Male and female were 44% and 56 % respectively. MASLD patients were categorized into 3 groups which were type 2 diabetes mellitus (T2DM) in 119 (41.6%), overweight or obese group in 149 (52.1%), and lean MASLD (BMI<23) in 18 (6.3%). Their baseline characteristics were shown in Table 1.

The average BMI was 41.3 kg/m² (range 19.1-88.7). Other metabolic abnormalities were hypertension in 165 (57.7%), and dyslipidemia in 157 (54.9%). There were 6 cirrhotic cases (2.1%) at diagnosis. Presence of advanced liver fibrosis (TE>12KPA) was found in 15 cases (5.2%). After a mean follow-up of 9.5 years (range 1-19); there were 11 cases (3.8%) developed coronary artery disease and 3 cases (1%) developed stroke. LRE. were present in 7 cases (2.4%) which included acute decompensation (3 cases; 1%), HCC (3 cases; 1%), and death (1 cases; 0.3%). The overall complications of LRE. or MACE. were present in 16 cases (5.6%). By using multivariate analysis, the predictors of LRE. or MACE. were in presence of hypertriglyceridemia (aOR 1.01 (1.00-1.01); p =0.002) and older age (aOR 1.06 (1.01-1.11); p =0.023).

Variables	T2DM (n=119)	Overweight/Obese (n=149)	Lean (n=18)	P value
Age (years)	53.2±15.0	46.1±13.2	62.5±10.1	<0.001
BMI (kg/m ²)	41.2±16.4	43.6±14.0	23.2±1.4	<0.001
Presence of DLP	84 (70.6%)	66 (44.3%)	7 (38.9%)	<0.001
AST (U/L)	45.1±30.0	38.7±33.5	75.7±57.1	<0.001
ALT (U/L)	64.7±42.6	61.6±47.7	94.8±50.9	0.01
Presence of advance fibrosis by TE>12 KPA (n=97)	9 (18.4%)	5 (13.2%)	1 (10.0%)	0.70
Presence of LRE.	9 (7.6%)	6 (4.0%)	1 (5.6%)	0.46
Presence of MACE.	7 (5.9%)	4 (2.7%)	1 (5.6%)	0.32

Conclusion: The overall complication of LRE. or MACE. was not uncommon (5.6% of this cohort with a mean follow-up of 9.5 years). Older age and hypertriglyceridemia were predictors of LRE. or MACE. occurrence.

Introduction: Recently, sub-classification of steatotic liver disease (SLD) has been updated by revising non-alcoholic fatty liver disease (NAFLD) as metabolic dysfunction-associated steatotic liver disease (MASLD). In this new nomenclature, emphasis was on the etiology of SLD, primarily at factors of metabolic syndrome and alcohol intake. However, associations between MASLD and gastrointestinal tract cancers other than liver cancer in relation to alcohol intake still require further analysis.

Aims & Methods: We investigated the relationship between the incidence of three gastrointestinal tract cancers (esophageal, stomach, and colorectal) and MASLD or alcohol related-SLD in diabetic patients. Using a retrospective screening cohort of National Health Insurance Service, individuals with type 2 diabetes from 2009 to 2012 were enrolled with their disease status being monitored until 2021. Fatty liver index (FLI) score described by Bedogni et al. (2006) was used to stratify the probability of hepatic steatosis. No steatosis (NS), indeterminate steatosis (IS), and steatosis-probable (PS) group were defined as FLI score 0 to < 30, 30< to ≤60, and >60, respectively. SLD was assumed if FLI score ≥ 30, and MASLD was defined as having at least 1 adult criteria provided by the American Association for the Study of Liver Diseases (AASLD). 2,746,079 subjects were classified into following subgroups: group 1: no steatosis, group 2: MASLD alone, group 3: MASLD with other liver disease, group 4: MASLD with heavy alcohol intake (metALD, 30-60g/d for men and 20-50g/d for women), and group 5: alcoholic liver disease (alcohol intake ≥ 60g/d for men and ≥50g/d for women) with metabolic syndrome. Adjusted hazard ratios (aHR) for each gastrointestinal tract cancer were estimated by incorporating multivariate Cox proportional hazards model.

Results: Compared with group 1 (reference), group 2 showed increased risks of stomach and colorectal cancers (aHR [95% confidence interval (CI)]: 1.06 [1.04-1.09] and 1.17 [1.14-1.19] respectively), but a decreased risk of esophageal cancer (0.81 [0.74-0.88]). In all gastrointestinal tract cancers, the risk of developing cancer compared to group 1 tended to increase from group 3 to group 5 (aHRs in groups 3, 4, 5: 1.40, 1.74, 2.36 in esophageal cancer; 1.13, 1.20, 1.22 in stomach cancer; 1.24, 1.33, 1.34 in colorectal cancer, respectively; all p for trend < 0.0001). Subgroup analysis by probability of steatosis in non-drinkers showed that stomach and colorectal cancer risk was positively correlated with higher likelihood of liver steatosis (aHR for NS, IS, PS: 1.00, 1.05, 1.11 for stomach cancer and 1.00, 1.15, 1.27 for colorectal cancer, respectively, p for trend < 0.05). However, this correlation was not demonstrated in esophageal cancer (aHR for NS, IS, PS: 1.00, 0.95, 1.08 for esophageal cancer).

Conclusion: In patients with diabetes, MASLD itself is associated with an increased risk of stomach and colorectal cancers but is likely associated with a reduced risk of esophageal cancer. Hepatic steatosis may be associated with higher risk of stomach and colorectal cancers, but not esophageal cancer. Amount of alcohol consumption is confirmed to increase the risk of these cancers regardless of the presence of SLD.

Introduction: With the implementation of the new nomenclature on steatotic liver disease (SLD), three main subgroups consisting of metabolic dysfunction-associated liver disease (MASLD), MASLD with increased alcohol intake (MetALD), and alcohol-related liver disease (ALD) have been defined. However, the risk of SLD for all-cause mortality and adverse outcomes as well as the different risks between MASLD, MetALD, and ALD needs further clarification.

Aims & Methods: Data from 13,599 participants without cancer of the population-based Gutenberg Health Study (baseline enrollment between 2007 and 2012) were cross-sectionally and prospectively analysed. The

fatty liver index (FLI) with a score of ≥ 60 was used to define SLD. The subgroups of SLD (MASLD, MetALD, and ALD) were defined according to the new nomenclature based on five cardiometabolic criteria and alcohol consumption.

The fibrosis-4 score (FIB-4) was calculated to determine patients at risk of fibrosis (≥ 1.3). All-cause mortality (10-year follow-up) and several adverse outcomes (hepatic decompensation, major adverse cardiac events (MACE), extrahepatic cancer) were analysed and compared across the subgroups of SLD.

Cox regression models were used to estimate adjusted hazard ratios (aHR) and their 95% confidence intervals (CIs). Adjustments were made for age, sex, socioeconomic status, education, and smoking.

Results: The overall prevalence of SLD was 37.3% (n=5,074), whereas the prevalence of MASLD, MetALD, and ALD were 30.5% (n=4,154), 5.3% (n=717) and 1.5% (n=202), respectively. Almost half of the population were women (48.9%, n=6,644), and the mean age was 54.3 (± 11.0) years. An elevated FIB-4 ≥ 1.3 was present in 20.2% (n=1,021) with SLD compared to 13.9% (n=1,184) without SLD (p<0.0001).

The cumulative incidence of all-cause mortality was higher in SLD and all its subgroups MASLD, MetALD, and ALD compared to no SLD (p<0.0001). Stratification by FIB-4 ≥ 1.3 revealed a higher risk of all-cause mortality across all investigated SLD subgroups compared to FIB-4 <1.3 (p<0.0001).

Each subgroup of SLD was associated with a higher risk of all-cause mortality: MASLD (aHR 1.6, 95% CI 1.4-1.9, p<0.0001), MetALD (aHR 1.6, 95% CI 1.3-2.1, p=0.00024) and ALD (aHR 1.6 95% CI 1.0-2.5, p=0.033).

The risk of adverse outcomes was increased in MASLD (hepatic decompensation: aHR 1.2, 95% CI 1.0-1.5, p=0.0045; MACE: aHR 1.5, 95% CI 1.2-1.8, p<0.0001; extrahepatic cancer: aHR 1.2, 95% CI 1.1-1.4, p=0.0086), whereas no differences were seen for MetALD and ALD.

Conclusion: The prevalence of SLD and especially MASLD is high in the general population. Patients with SLD and any of its three main subgroups show a higher risk of all-cause mortality, whereas the risk for adverse outcomes is particularly increased in those with MASLD. These results highlight the importance of screening for SLD and related risk factors to improve outcomes.

NON-INVASIVE FIBROSIS ASSESSMENT IN TYPE 2 DIABETIC PATIENTS WITH MASLD: A RISK STRATIFICATION APPROACH

L. Khayat¹, I. Jemni², L. Safer³

¹CHU Fattouma Bourguiba, Monastir, Tunisia, ²CHU Fattouma Bourguiba, Gastroenterology, Monastir, Tunisia, ³CHU Fattouma Bourguiba, Les Berges Du Lac, Tunisia

Introduction: The development and validation of non-invasive fibrosis tests have transformed clinical practice in hepatology in recent years. Metabolic-associated fatty liver disease (MASLD), formerly known as non-alcoholic fatty liver disease (NAFLD), is currently the most prevalent liver disease.

In this study, our aim was to evaluate the utility of non-invasive tests in the diagnosis and staging of fibrosis in type 2 diabetic (T2D) patients with hepatic steatosis.

Aims & Methods: This was a prospective cross-sectional study that included 122 T2D patients over a 10-month period. Hepatic steatosis was confirmed by abdominal ultrasound or a FLI score ≥ 60 . We used non-invasive tests including the serum marker FIB-4, transient elastography FibroScan®, and the combined Agile -3 score.

Interpretation of the scores was as follows:

For FIB-4, < 1.3 indicated a low risk of advanced fibrosis, 1.3–2.67 indicated an intermediate risk of advanced fibrosis, and > 2.67 indicated a high risk of advanced fibrosis. For FibroScan, minimal or absent fibrosis (F0-F1) was defined by a LSM value <8 kPa, moderate hepatic fibrosis (≥F2) by a LSM value between 8–9.6 kPa, and advanced fibrosis by a hepatic elasticity LSM >9.6 kPa. For the Agile -3 score, a value < 0.451 excluded advanced fibrosis (F3) and a value ≥ 0.679 confirmed advanced fibrosis (F3).

Results: The average age was approximately 60 years with a female predominance. The FIB-4 score ranged from 0.311 to 4.01, with an average of 1.0881. 73.77% of patients had a FIB-4 indicating no fibrosis. 2.45% had advanced fibrosis, and 23.77% were in an indeterminate FIB-4 score range. The FIB-4 score had a positive predictive value (PPV) of 42.86% and a negative predictive value (NPV) of 77.23% for detecting significant fibrosis. Regarding advanced hepatic fibrosis, FIB-4 had a PPV of 45.45% and an NPV of 75.67%. Hepatic elasticity ranged from 1.5 to 75 kPa with an average of 6.62 kPa. 82.78% had no fibrosis, 8.19% had significant fibrosis, and 9.01% had advanced fibrosis. To reduce the grey zone, we calculated the AGILE-3 score, which was observed in a range from 0.03 to 1. It reduced the grey zone by up to 40%. Among the 10 patients in the grey zone on FibroScan, 3 were reclassified to fibrosis F3 by the AGILE-3 score, 4 remained in the grey zone, and 3 were reclassified to absent or minimal fibrosis.

Conclusion: The implementation of approaches using non-invasive tests is generally a promising strategy in the management of MASLD in primary care, providing clinically effective and cost-effective pathways to identify patients at risk of advanced fibrosis and streamline referrals to secondary care, subsequently benefiting from accurate risk assessments without the need for liver biopsies. Our study suggests the sequential use of non-invasive tests, starting with FIB-4 which, according to our study, has an NPV of over 75% to rule out advanced or significant fibrosis, followed by sequential use of FibroScan and Agile 3+ score to better reduce the grey zone, hence limiting the need for liver biopsies.

ALCOHOL-INDUCED DEREGLATION OF IMMUNE-METABOLIC FUNCTIONS EXACERBATES ATHEROSCLEROSIS DEVELOPMENT IN A NOVEL MURINE MODEL FOR METALD

C. Hoebinger¹, D. Rajčić¹, L. Goederle¹, T. Hendrikx¹

¹Medical University of Vienna, Department of Laboratory Medicine, Vienna, Austria

Contact E-Mail Address: constanze.hoebinger@meduniwien.ac.at

Introduction: The recently revised nomenclature of steatotic liver disease differentiates between metabolic dysfunction-associated steatotic liver disease (MASLD) and alcohol-related liver disease (ALD), besides introducing the newly termed MetALD for patients with MASLD combined with moderate alcohol consumption. While this re-classification acknowledges alcohol as an important contributor to liver disease pathogenesis, a better understanding of the underlying mechanisms that might distinguish MetALD is necessary to identify novel targets to improve diagnosis and intervention for these distinct patients.

Aims & Methods: Here, we aimed to investigate ethanol-mediated immune-metabolic effects by utilizing dyslipidemic low-density lipoprotein receptor-deficient mice (*Ldlr*^{-/-}) in a novel murine model for MetALD. Hence, *Ldlr*^{-/-} mice, displaying a human-like systemic lipid profile, were fed a high-fat, high-cholesterol (HFC) diet for eight weeks in combination with regular or ethanol-containing drinking water (alternating 10–20% v/v) to induce MASLD and MetALD, respectively. To investigate the contribution of ethanol-induced dysbiosis, additional cohorts underwent similar dietary interventions in combination with broad-spectrum antibiotics to deplete the microbiome.

Results: Despite a similar body weight gain, ethanol intake by HFC-fed *Ldlr*^{-/-} mice resulted in heavier liver weights and heightened hepatic lipid levels, indicating enhanced steatosis compared to mice receiving regular drinking water. Gene expression analysis revealed alterations in lipid metabolism in the livers of ethanol-consuming HFC-fed *Ldlr*^{-/-} mice. In line, *Ldlr*^{-/-} mice exposed to ethanol had increased cholesterol, triglyceride, and free fatty acid levels in circulation, suggesting systemically enhanced dyslipidemia upon alcohol consumption. Furthermore, ethanol-treated mice recruited more inflammatory Ly6C^{high} monocytes to the liver and displayed higher hepatic gene expression of various pro-inflammatory markers, including *Il1b*, *Cxcl2*, and *Ccl2*, suggesting accelerated liver disease progression in mice with MetALD. Moreover, elevated hepatic inflammation was reflected systemically as HFC-fed *Ldlr*^{-/-} mice consuming ethanol showed increased monocytois in circulation. Notably, this was associated with enlarged lesion size in the aortic root of HFC-fed *Ldlr*^{-/-} mice receiving ethanol, which occurred independently of the elevated dyslipidemia, indicating a direct immunomodulatory effect of ethanol on atherosclerosis progression in mice developing MetALD compared to MASLD. While ethanol intake induced intestinal dysbiosis, microbiome depletion with broad-spectrum antibiotics, either from the start or during the last two weeks of the dietary intervention, did not mitigate the enhanced progression of steatohepatitis and elevated systemic monocytois in our murine MetALD model compared to MASLD-developing *Ldlr*^{-/-} mice.

Conclusion: Our findings demonstrate that alcohol consumption during metabolically-associated dysfunction serves as a critical lifestyle factor with immunomodulatory effects, independent of microbiota alterations. Alcohol significantly influences the progression of steatotic liver disease and atherosclerosis, thereby suggesting a heightened risk of cardiovascular events in patients with MetALD.

Disclosure: Nothing to disclose.

Introduction: ESSENCE (NCT04822181) is an ongoing 247-week Phase 3, randomised, placebo-controlled trial evaluating the effect of the glucagon-like peptide-1 analogue, semaglutide 2.4 mg subcutaneous once weekly (OW) in participants with non-cirrhotic metabolic dysfunction-associated steatohepatitis (MASH). We report the baseline characteristics of the randomised participants.

Aims & Methods: Following a 14-week screening phase, 800 participants (part 1) of 1200 planned (part 2) with MASH and fibrosis stages 2/3 (F2/F3) were randomised 2:1 to receive semaglutide 2.4 mg subcutaneous OW or placebo OW added to standard of care. In part 1, the two primary endpoints at 72 weeks are resolution of steatohepatitis and no worsening of liver fibrosis, and improvement in liver fibrosis and no worsening of steatohepatitis. Based on a central pathologist evaluation, inclusion criteria were histological presence of steatohepatitis stages F2/F3 per the Non-alcoholic Steatohepatitis Clinical Research Network classification, and a non-alcoholic fatty liver disease activity score (NAS) of ≥ 4 , with a score of ≥ 1 in steatosis, lobular inflammation and hepatocyte ballooning.

Results: 800 participants (250 F2; 550 F3) were randomised. Mean (SD) age was 56 (11.6) years; 57.1% were female; $\geq 99\%$ had ≥ 1 cardiometabolic risk factor(s) in accordance with the metabolic dysfunction-associated steatotic liver disease (MASLD) definition. Mean (SD) NAS was 5.05 (0.95), and higher in F3 versus F2 (5.11 [0.95] vs 4.92 [0.93], respectively). Notably, participants with a higher NAS had more cardiometabolic risk factors for MASLD (52.9% with NAS ≥ 5 vs 45.3% with NAS 4). Similarly, a greater proportion of participants with F3 had all five cardiometabolic risk factors versus F2 (52.9% vs 44.8%, respectively). Although cardiometabolic comorbidities were highly prevalent, 44.5% of participants did not have type 2 diabetes (T2D), and 27.3% did not have obesity. Normal liver transaminases were observed in 26.3% of participants (28% F2; 26% F3). Mean

(SD) FibroScan liver stiffness was 12.8 (6.9) kPa, and values of < 8 kPa were observed in 15.3% of participants. Mean (SD) controlled attenuation parameter value was 329 (46) dB/m; mean (SD) enhanced liver fibrosis (ELF) score was 10.0 (1.0), and 43.5% of participants had an ELF score of < 9.8 . Overall, 8.8% and 9.0% of participants with/without T2D did not meet any of the following non-invasive criteria: Fibrosis-4 index ≥ 1.3 , vibration-controlled transient elastography ≥ 8.1 , or ELF ≥ 9.8 , and more participants with F2 (14.7–16.4%) did not meet these criteria versus F3 (4.5–6.7%).

Conclusion: The ESSENCE baseline population includes participants with significant fibrosis (F2 and F3) and approximately 91% of the trial population had ≥ 1 positive diagnostic non-invasive test. Cardiometabolic risk factors were found in $\geq 99\%$ of participants, and in increased numbers in those with higher NAS and fibrosis stages.

This is an encore of an abstract that will be presented for the first time at the European Association for the Study of the Liver (EASL) Congress, 5–8 June 2024, Milan, Italy.

Introduction: IPMN are considered a possible cause of acute pancreatitis (AP) due to a transient obstruction of the pancreatic duct by mucin. IPMN-associated-AP is considered a relative indication to surgery for both, prevention of recurrent attacks of pancreatitis and for a hypothesized increased risk of cancer. The published literature is based on surgical series with significant population heterogeneity including MD-IPMN, mixed-type-IPMN and BD-IPMN. No data are available on the clinical features of this particular type of AP, on the risk of recurrent pancreatitis and pancreatic cancer in patients with BD-IPMN-associated-AP.

Aims & Methods:

The aim of this study is the description of clinical and radiological features of BD-IPMN-related AP.

All patients with AP associated to BD-IPMN without "worrisome features" and "high risk stigmata" and no other identifiable causes of AP evaluated at Gastroenterology Unit of the University of Verona between January 1st 2012 and December 31st 2022 were retrospectively identified and analyzed.

Results: One-hundred-thirty-five patients were included (54.8% males and 45.2% females), with mean age at the first episode of AP of 55.8 ± 12.5 years. Pancreatic necrosis was diagnosed in 15 patients (11.1%) and only 1 patient (0.7%) was admitted in Intensive Care Unit. One-hundred-two (75.6%) had recurrent pancreatitis.

The median size of the largest BD-IPMN was 8 mm (IQR 7). None had mural nodules, thickened cystic walls, or dilated main pancreatic duct ≥ 5 mm. Eighteen patients (13.3%) developed main pancreatic duct dilation ≥ 5 mm. None developed dilation of main pancreatic duct ≥ 10 mm, mural nodules, thickened cystic walls, or jaundice. At Cox unadjusted analysis no BD-IPMN-related features were associated to increased risk of recurrent pancreatitis. Surgical resection was performed in 10 patients (7.4%). None developed pancreatic cancer or signs of chronic pancreatitis during follow-up.

Conclusion: BD-IPMN-associated AP has a benign clinical course. Cystic features are not related to increased risk of recurrence. Cancer risk appears extremely low in patients with BD-IPMN-associated-AP.

Disclosure: Nothing to disclose.

RISK FACTORS FOR PANCREATIC CANCER IN PATIENTS WITH DIABETES MELLITUS: A JAPANESE POPULATION-BASED STUDY USING THE SHIZUOKA KOKUHO DATABASE

T. Satoh^{1,2}, E. Nakatani², S. Kawaguchi¹, K. Ohno¹, T. Usui^{2,3}

¹Shizuoka General Hospital, Department of Gastroenterology, Shizuoka, Japan, ²Shizuoka Graduate University of Public Health, Graduate School of Public Health, Shizuoka, Japan, ³Shizuoka General Hospital, Research Support Center, Shizuoka, Japan

Contact E-Mail Address: tatsunori-sato@i.shizuoka-pho.jp

Introduction: Pancreatic cancer (PC) are associated with notably poor prognoses. The clinical practice guidelines for PC list several risk factors of PC, including diabetes among them. Diabetic patients, who regularly visit the hospital, present a practical opportunity for pancreatic surveillance. Effective surveillance for PC could be achieved by identifying diabetic patients at high-risk for PC who already require regular hospital visits. Nevertheless, there is a notable lack of research on pancreatic cancer risk factors within the diabetic population.

Aims & Methods: This study aimed to identify risk factors for pancreatic cancer in diabetic patients using a longitudinal cohort from the Shizuoka Kokuho database, spanning April 2012 to September 2021. Diabetic patients were identified and monitored for the onset of pancreatic cancer. Factors analyzed included age, sex, the Elixhauser comorbidity index, and specific comorbidities. Statistical analyses involved univariate and multivariate Cox proportional hazards regression.

Results: The Shizuoka Kokuho database, which comprises 2,654,567 individuals, identified 212,775 as diabetic patients. Of these patients, 1,755 developed pancreatic cancer during the observation period, which had a median duration of 5.1 years and a maximum of 8.5 years. The annual incidence rate of pancreatic cancer in this group was 166.7 cases per 100,000 person-years [95% CI: 158.9–174.5].

Identified candidate risk factors included older age, male sex, coexisting liver disease, cardiac arrhythmias, hypertension, chronic pancreatitis, and pancreatic cystic lesions, each with *p*-values below 0.05. These variables were subsequently incorporated into a multivariate model.

The multivariable regression results indicated that older age and male gender were associated with an increased risk of pancreatic cancer (HR: 1.267 [95% CI: 1.150–1.395]). Liver disease emerged as a notable risk factor (HR: 1.13 [95% CI: 1.01–1.26]). Significant correlations were found between the onset of PC and both chronic pancreatitis (HR: 1.98 [95% CI: 1.48–2.64]) and pancreatic cystic disease (HR: 4.79 [95% CI: 3.43–6.67]). Neither the type of diabetes nor the presence of diabetic comorbidities was associated with the onset of PC.

Conclusion: This cohort study has identified key risk factors for pancreatic cancer in diabetic patients. Findings indicate that advanced age, male sex, a history of liver disease, chronic pancreatitis, and pancreatic cystic lesions significantly increase the risk of pancreatic cancer in this population. These insights underscore the importance of targeted surveillance for early detection of pancreatic cancer in diabetic patients, particularly those with these risk factors.

Introduction: The prognostic significance of the preoperative C-reactive protein-albumin-lymphocyte (CALLY) index has been reported in various cancer types; however, its role in pancreatic cancer remains unclear.

Aims & Methods: A cohort of 339 patients with resectable pancreatic cancer (RPC) who underwent curative surgery between July 2012 and December 2019 was analyzed. The CALLY index was defined as (albumin × lymphocytes)/ (C-reactive protein × 10⁴). The cutoff value of the CALLY index was determined according to receiver operating characteristics analysis using survival status at the 3-year follow-up.

We investigated the association between the CALLY index with disease-free survival (DFS) and overall survival (OS) using univariate and multivariate analyses.

Results: The median CALLY index was 4.1, with an interquartile range of 1.4–11.7. The cutoff value of the CALLY index was set at 3.0, dividing the patients into the CALLY-high group (> 3.0; n = 198) and the CALLY-low group (≤ 3.0; n = 141). The DFS and OS in the CALLY-low group were significantly worse than those in the CALLY-high group ($p < 0.001$ and $p < 0.001$, respectively). Multivariate analysis, using the preoperative clinicopathological variables, indicated that the CALLY index ≤ 3.0 was an independent prognostic factor for DFS (Hazard Ratio [HR] 1.53, $p = 0.008$) and for OS (HR 1.69, $p = 0.002$).

Conclusion: In RPC, survival outcomes were significantly stratified by the CALLY index = 3.0, with < 3 being a significantly poor prognostic factor for DFS and OS. The CALLY index may be useful in predicting the long-term survival of patients with RPC.

Disclosure: Nothing to disclose.

DIAGNOSTIC AND PROGNOSTIC ACCURACY OF MICRORNAS IN PANCREATIC CANCER: A SYSTEMATIC REVIEW AND META-ANALYSIS

F. Hasani¹, M. Masrour², S. Khamaki¹, K. Jazi³, S. Hosseini¹, H. Heidarpour¹

Contact E-Mail Address: fatemehassani2001@gmail.com

Introduction: Pancreatic cancer (PC) remains a significant contributor to cancer mortality globally, with limited effective diagnostic and prognostic tools. MicroRNAs (miRNAs) have emerged as promising biomarkers for PC diagnosis and prognosis due to their stable presence in body fluids and regulatory role in gene expression. This systematic review and meta-analysis aim to evaluate the diagnostic and prognostic accuracy of miRNAs in PC based on existing literature.

Aims & Methods: A comprehensive literature search was conducted in PubMed, Web of Science, and Scopus databases. Studies reporting sensitivity, specificity, or area under the curve (AUC) values for miRNAs in PC diagnosis, as well as hazard ratios (HRs) for survival evaluations for prognosis, were included. Data extraction and quality assessment were

performed following PRISMA guidelines. Meta-analyses were conducted using appropriate statistical methods. The protocol has been registered in PROSPERO.

Results: Diagnostic analysis included 290 evaluations, revealing an overall AUC of 0.8226 for PC diagnosis. Subgroup analyses based on specimen type demonstrated varying diagnostic accuracies, with blood and tissue specimens showing higher AUC values. Promising miRNAs with AUC values above 0.8 included miR-320, miR-1290, miR-93, miR-25, miR-451, miR-20, miR-21, miR-223, and miR-122.

Prognostic analysis encompassed 46 studies, indicating significant associations between miRNA expression and overall survival (OS) and progression-free survival (PFS). The combined hazard ratio (HR) for studies reporting OS HRs higher than one was 1.7613 (95% CI: 1.5394–2.0152, $p < 0.0001$; I² = 81.7%). Notable miRNAs with prognostic significance included miR-10 (Pooled HR [95% CI] 2.3538 [0.8241–6.7229]), miR-21 (Pooled HR [95% CI] 1.9027 [0.8293–4.3652]), and miR-221 (Pooled HR [95% CI] 1.5022 [1.1424; 1.9754]). Studies reporting OS HRs less than one had a pooled HR of 0.6805 (95% CI: 0.5862–0.7901, $p < 0.0001$; I² = 65.4%), indicating favorable prognostic significance.

Conclusion: MiRNAs hold promise as diagnostic and prognostic biomarkers for PC. Blood and tissue specimens offer superior diagnostic accuracy, while several miRNAs show potential for predicting patient outcomes. Further research and validation are warranted to establish miRNAs' clinical utility in PC management.

Disclosure: Nothing to disclose.

VALIDATION OF KYOTO CONSENSUS GUIDELINE FOR INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM OF THE PANCREAS IN SMALL UNCHANGED BD-IPMN AFTER 5 YEARS SURVEILLANCE

M. Marasco¹, M. Signoretti¹, R. Di Pangrazio¹, M. Casella¹, M. Rinzivillo¹, B. Annibale¹, F. Panzuto¹

¹Digestive Disease Unit, Sant'Andrea University Hospital, Department of Medical Surgical Sciences and Translational Medicine, Sapienza University, Rome, Italy

Contact E-Mail Address: matteomarasco93@gmail.com

Introduction: Intraductal papillary mucinous neoplasm (IPMN) of the pancreas represents around 80 % of incidental-discovered cysts and one of the most frequent causes of access for pancreatic clinical evaluation. Fukuoka guidelines (2017) have been the clinical reference point until the recently published Kyoto guidelines (2024) that bring out various new key points including “stop surveillance” concept as an appropriate approach in specific patients.

Aims & Methods: The aim of the study is to observe clinical validity of new recommendations of Kyoto guidelines, particularly in patients with unchanged BD-IPMN ≤ 20 mm after 5 years of surveillance. This is an observational retrospective single-center study. Patients were evaluated in our Digestive Disease Unit from Jan 2018 to Jan 2024 and they were handled according to Fukuoka guidelines.

Results: A total of 163 patients (M: F=56:107) with a median age of 70 y/o (44-92). BD-IPMN were 152 (93.5%), located in the pancreatic head (70, 46%), body (63, 41.4%) and tail (19, 12.5%). During surveillance, 29 (18%) and 3 (2.2%) patients developed, respectively, ‘worrisome features’ (WF) and ‘high-risk stigmata’ (HRS). Overall, 39 (23.9%) patients underwent surveillance for ≥ 5 years. Particularly, 20 (51.3%) of these patients had BD-IPMN ≤ 20 mm unchanged during a median time follow-up of 77 months (60-144): median IPMN dimension was 12 mm (7-20) and median age was 71 y/o (59-87). They performed a median of 7 (3-10) exams (RMN, CT, EUS) with no evidence of WF or HRS beyond 5 years of follow-up. How-

ever, in IPMN ≥ 20 mm with surveillance ≥ 5 years, 14 (35.8%) and 2 (5.1%) patients developed, respectively, WF and HRS at a median of 22 months (6-120) from diagnosis with consequent different timing of follow-up or surgical strategy.

Conclusion: Based on our experience, no one patient with BD-IPMN ≤ 20 mm during FU ≥ 5 years developed any WF or HRS. This confirmed the latest points of view of Kyoto guidelines, providing patients the possibility to stop surveillance. This could have an important role in the patient's psychological aspects and in decreasing request overload of radiological or endoscopic exams.

Introduction: Early detection of pancreatic cancer (PC) can significantly improve patient outcomes.

Aims & Methods: In 2007, the Onomichi Medical Association initiated a social program aimed at enhancing early PC diagnosis by fostering collaboration between PC specialists from medical centers and general practitioners. Initially, specialists educated general practitioners on PC risk factors, emphasizing elevated serum pancreatic enzyme levels, ultrasound (US) findings such as pancreatic duct dilation, and the importance of magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound (EUS) for detecting early-stage PC. Upon encountering suspicious cases, general practitioners referred patients to specialists for further evaluation. A retrospective study was conducted, involving patients who underwent surgery and were diagnosed with PC at Onomichi General Hospital between January 2007 and December 2022.

Results: During this period, 28,185 patients sought consultation for suspected PC, with 9,420 undergoing CT scans. Additionally, 11,781 patients with main pancreatic duct (MPD) dilation underwent MRCP. CT and MRCP identified features suggestive of PC, prompting EUS examinations in selected patients. EUS-guided fine needle aspiration (FNA) was performed in 808 cases where tumor lesions were detected and deemed suitable for sampling. For cases with negative EUS-FNA results, undetected lesions on EUS, or lesions too small for EUS-FNA, endoscopic retrograde cholangiopancreatography (ERCP) with pancreatic juice cytology was conducted in 945 cases. Histological diagnosis confirmed PC in 813 cases, with 334 patients undergoing surgery. Among them, 140 cases were early-stage PC,

comprising 41 stage 0 and 99 stage I cases. The 5-year survival rate for PC cases diagnosed from 2011 to 2016 was 17.9%, showing improvement to 21.4% for cases diagnosed in 2017.

Conclusion: This collaborative early diagnosis program, emphasizing risk factor awareness and interdisciplinary cooperation within regional healthcare networks, highlights promising prospects for enhancing PC prognosis.

Disclosure: Nothing to disclose.

Introduction: Pancreatic cancer is estimated to be the second leading cause of cancer-related deaths in Europe by 2030 and remains a significant challenge with limited risk factors. Pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasms (IPMN), and mucinous cystic neoplasia (MCN) are three common precursor lesions for this disease. The risk of pancreatic cancer in first-degree relatives (FDRs) of individuals with precursors however remains unknown.

Aims & Methods: This study aims to analyze the absolute incidence and relative risk of pancreatic cancer by family history of precursors using a population-based cohort study in Sweden. We included all patients who had been pathologically diagnosed with precursor lesions of pancreatic cancer between 1965 and 2016 in Sweden and up to 5 matched reference individuals from the general population based on birth year, sex, calendar year, and residency. We identified all their FDRs (parents, full siblings, and offspring) using the Swedish multigeneration registry. All FDRs were followed up through national registries from birth or year 1959 when cancer registry was launched, until the date of pancreatic cancer diagnosis, death, migration, or end of follow-up (January 1st, 2020). The absolute cancer incidence rate was computed as the number of observed cases divided by person-years and relative risk was calculated as multivariable-adjusted hazard ratio (HR) using Cox proportional hazards regression.

Results: A total of 27,862 FDRs were included in the analyses, among which 4647 were FDRs of 1036 precursor patients and 23,157 were FDRs of 5067 matched reference individuals. During the follow-up, 149 FDRs developed pancreatic cancer, with an incidence rate of 10 (95% CI 8-12) per 100,000 person-years for FDRs of reference individuals, and 21 (16-28) for FDRs of precursor individuals. Compared to FDRs of reference individuals, FDRs of precursor had a 2.24 (1.58-3.18) times higher risk of developing pancreatic cancer during their lifetime. When stratified by subtype of precursors, similar HRs were found for PanIN (2.37 [1.52-3.70]) and IPMN (2.31 [1.29-4.11]), but not for MCN (1.84 [0.89-3.78]). Individuals whose parents had been diagnosed with precursors had 4.94 (2.10-11.62) times higher

risk for pancreatic cancer than those without. To facilitate clinical application, we also assessed the association of pancreatic cancer risk after known diagnosis of precursors in FDRs. Compared to reference counterparts, an HR of 4.46 (2.37-8.38) was found for those with known precursors in FDRs.

Conclusion: A family history of precursor lesions of pancreatic cancer can be an indicative risk factor for pancreatic cancer and risk estimates varies by precursor subtypes and type of FDRs with precursors. Precursor lesions in FDR should be considered as a positive phenotype in individuals at risk.

Contact E-Mail Address: gaetanolauri.94@gmail.com

Introduction: Hormonal exposure influences cancer initiation and progression in several organs, including the pancreas. The association between gynecological factors and the onset of pancreatic adenocarcinoma (PDAC) is conflicting, with some studies showing a reduced risk of PDAC with the use of hormonal replacement therapy (HRT) or with having had a late-onset menopause. Nonetheless, the association between gynecological factors and disease prognosis has not yet been investigated. Our objective was to evaluate whether gynecological/reproductive factors affect PDAC prognosis.

Aims & Methods: This was a single-center retrospective analysis of a prospectively maintained database of PDAC patients. Risk factors were assessed via questionnaires regarding gynecologic/reproductive factors (age at menarche, menopause, years of fertility, breastfeeding, pregnancy, miscarriages, use of oral contraceptives (OC) or HRT), medical history, and prognosis were evaluated with follow-up visits and/or telephonic calls. Continuous variables were investigated using the Mann-Whitney test, and factors associated with survival probability were evaluated using Cox's proportional hazards model, adjusting for potential confounders.

Results: 228 PDAC women were analyzed, with mean age at diagnosis being 68. The most frequent stages were borderline resectable (35.9%) and locally advanced (25.4%), with a median overall survival (OS) of 14 months. The age of PDAC onset for patients with previous use of OC was significantly lower than that of non-users (63 years vs. 72; $p < 0.0001$), and OC use was associated with a trend toward increased survival (HR 0.6; 95%CI: 0.35-1.03; $p = 0.06$). In addition, previous use of HRT was associated

with a reduced risk of recurrence or progression (HR, 0.4; 95%CI: 0.26-0.99; $p = 0.001$). No differences in survival or progression-free probability were observed with the other factors.

Conclusion: This is the first study to evaluate whether gynecological/reproductive factors are associated with the prognosis of PDAC patients, with the use of OC and HRT being the most relevant factors. Previous OC users had a significantly lower onset age for PDAC and a borderline significant association was seen with increased survival. Additionally, HRT use is associated with a reduced risk of tumor recurrence or progression. These data need to be confirmed, and the potential mechanisms need to be elucidated.

Disclosure: Nothing to disclose.

PROTEIN N-GLYCOSYLATION TRAITS CAN ACCURATELY DISTINGUISH PANCREATIC CANCER CASES FROM A HETEROGENEOUS GROUP OF CONTROLS

A. Bogdanski^{1,2}, D. Klatte^{1,2}, Y. Bi¹, K. Clift¹, J. van Hooft², M. van Leerdam^{2,3}, M. Wührer⁴, M. Wallace¹, Y. van der Burgt⁴
¹Mayo Clinic, Gastroenterology and Hepatology, Jacksonville, United States of America, ²Leiden University Medical Center, Gastroenterology and Hepatology, Leiden, Netherlands, ³Netherlands Cancer Institute, Gastrointestinal Oncology, Amsterdam, Netherlands, ⁴Leiden University Medical Center, Center for Proteomics and Metabolomics, Leiden, Netherlands

Contact E-Mail Address: a.m.bogdanski@lumc.nl

Introduction: New methods are urgently needed to detect pancreatic ductal adenocarcinoma (PDAC) at an earlier stage to improve outcomes.¹

²We have previously reported six protein N-glycosylation traits (NGTs) and further grouped these into three biologically distinct ones to discriminate PDAC patients from healthy controls with an area under the curve (AUC) of 0.81-0.88.³ A subsequent longitudinal study revealed glycosylation differences up to 50 months prior to diagnosis, indicating potential for early detection.⁴ However, external validation is needed to determine accuracy of this biomarker panel. Moreover, it is unknown whether this panel can differentiate PDAC in a diverse group that resembles clinical practice better. Therefore, this study aims to validate the biomarker panel in a heterogeneous cohort.

Aims & Methods: Protein N-glycans in prospectively collected plasma samples from Mayo Clinic were analyzed by mass spectrometry at the Leiden University Medical Center using a semi-automated preparation protocol.⁵ Glycosylation profiles were determined and compared between PDAC cases and controls. The control group consisted of imaging-confirmed pancreatic disease-negative controls and individuals with benign pancreatic diseases, including (non)-mucinous cysts and pancreatitis. Logistic regression was performed to calculate odds ratios (ORs) for the six previously reported protein NGTs. Additionally, AUC, sensitivity and specificity were calculated to determine the accuracy of the three biologically distinct NGTs (antennarity (CA4), sialylation (A3F0L), and fucosylation (CFa)) in discriminating PDAC cases from controls.

Results: We included 232 individuals, of whom 42 (18.1%) were diagnosed with PDAC, and 190 (81.9%) served as controls. Among controls, 59 (31.1%) were pancreatic disease-negative and 131 (68.9%) had benign pancreatic diseases. Median age of PDAC cases and controls was 71.7 (IQR=14.5) and 65.5 years (IQR=17.6), respectively. Among PDAC cases, 19 (45.2%) were female, and 106 (52.2%) among controls. The BMI in PDAC cases and controls was equal (26.8 (IQR=7.0) and 26.6 (IQR=7.6), respectively). Table 1 shows ORs for the six NGTs and PDAC. The AUC for the three biologically distinct traits was 0.77 (95% CI: 0.69-0.86), with a sensitivity of

0.81 (95% CI: 0.69-0.93) and specificity of 0.70 (95% CI: 0.64-0.76). When comparing PDAC cases to pancreatic disease-negative controls, the AUC was 0.83 (95% CI: 0.74-0.92), with a sensitivity of 0.79 (95% CI: 0.64-0.90) and specificity of 0.80 (95% CI: 0.69-0.90).

Variables	PDAC compared to Heterogeneous cohort		PDAC compared to pancreatic disease-negative cohort	
	Odds ratio (95% CI)	P-value	Odds ratio (95% CI)	P-value
CA2	0.90 (0.85-0.95)	<0.001	0.86 (0.79-0.93)	0.001
CA4	1.59 (1.30-1.97)	<0.001	2.08 (1.49-3.10)	<0.001
CFa	1.76 (1.28-2.47)	0.004	3.40 (1.86-7.15)	0.002
A3F0L	0.91 (0.84-0.97)	0.043	0.82 (0.72-0.91)	0.005
A3F0E	1.17 (1.07-1.29)	0.004	1.37 (1.18-1.64)	0.001
A3FE	1.90 (1.39-2.66)	0.001	2.58 (1.69-4.23)	<0.001

Table 1: The odds ratios for six glycosylation traits distinguishing pancreatic ductal adenocarcinoma cases from a heterogeneous cohort, including pancreatic disease-negative and benign pancreatic diseases controls. A subanalysis was performed for disease-negative controls. The Bonferroni correction was used to account for multiple testing. Abbreviations: PDAC= pancreatic ductal adenocarcinoma, CI= confidence interval.

Conclusion: Distinctive NGTs from plasma protein differentiate PDAC from non-PDAC in a diverse group, consisting of cystic pancreatic diseases and pancreatitis. This panel holds potential for future early detection methods.

REDUCED RISK OF PANCREATIC CANCER ASSOCIATED WITH REGULAR ASPIRIN USE IN TYPE 2 DIABETES PATIENTS

J.T. Tan¹, K.-S. Cheung^{1,2}, X. Mao^{2,1}, W.-K. Seto^{1,2}

¹The University of Hong Kong, Department of Medicine, Hong Kong, Hong Kong, ²The University of Hong Kong-Shenzhen Hospital, Department of Medicine, Shenzhen, China

Contact E-Mail Address: tjt97@connect.hku.hk

Introduction: Diabetes mellitus (DM) is a substantial risk factor for pancreatic cancer (PC). Concurrently, aspirin has been implicated to have chemopreventive effect against cancer of digestive system. However, studies regarding the effect of aspirin on mitigating PC risk among DM populations remain scant.

Aims & Methods: We aimed to examine whether regular use of aspirin was associated with a reduced risk of PC after adjusting for known risk factors among type 2 diabetes (T2D) patients.

This was a territory-wide, retrospective cohort study of newly diagnosed T2D patients between 2001 and 2015 in Hong Kong. Exclusion criteria included <18 years old, history of PC, pancreatic neuroendocrine tumor, serous cystadenoma, chronic or acute pancreatitis, and pancreatic cyst. The outcome of interest was pancreatic cancer. Adjusted hazard ratios (aHRs) for outcomes associated with aspirin use were calculated using multivariable Cox regression models. Aspirin use was treated as a time-varying covariates (≥ 180 days use at each yearly interval) in the analysis to address and minimize immortal-time bias.

Results: We identified 342,920 T2D patients (52.2% male, mean age: 58.8 $\pm$ 11.6 years), including 43,634 (12.7%) aspirin users. During a mean follow-up of 11.1 $\pm$ 4.2 years, 1,114 (0.3%) patients developed PC, with an incidence rate of 2.92 per 10,000 person-years. Aspirin use was associated with a reduced PC risk (HR 0.55, 95%CI 0.46-0.66). When compared with the reference group (never use), a lower risk was observed with increasing frequency, with the exception of daily use. In addition, longer durations of aspirin use were associated with a progressively lower PC risks (HR 0.83, 95%CI 0.71-0.96, for less than five years of use; HR 0.56, 95%CI 0.45-0.69, for five to ten years of use; and HR 0.27, 95%CI 0.20-0.36, for ten or more years of use. Both frequency and duration of aspirin use demonstrated statistically significant trends ($P_{\text{trend}} < 0.001$) (Table 1).

Aspirin use	No. of patients (n=342,920)	No. of PC (n=1,114)	HR (95% CI)	P*	P _{trend}
Frequency					
Never user	219,674	736	ref	-	<0.001

Table 1. HRs and 95% CIs for the association between frequency and duration of aspirin use and risk of pancreatic cancer.

*Cox proportional hazards model was used to calculate the P values. Adjusted covariates included age, sex, lifestyle factors (body mass index, smoking, and alcohol use), metabolic disorders (dyslipidemia and hypertension), time-weighted mean HbA1c, DM complications, cardiovascular diseases, other anti-diabetic medications, non-aspirin non-steroidal anti-inflammatory drugs, and statins.

Abbreviation: CI, confidence interval; HR, hazard ratios; PC, pancreatic cancer; ref, reference

Conclusion: Aspirin use was associated with a reduction in PC risk among T2D patients, which was dependent on both frequency and duration of use. Notably, this trend was observed with increased frequency of use, with the exception of daily use. Further studies are warranted to assess long-term effects and potential risks.

Disclosure: Nothing to disclose.

Introduction: Celiac disease (CeD) is a common autoimmune disease among Caucasian people. It had been occasionally reported in southern China. However, cases of celiac disease are more common in the north-west region.

Aims & Methods: In order to elucidate the potential pathogenesis of celiac disease in the Chinese patients, metabolomics could be the good approaches for primary study. We used pseudotargeted metabolomics techniques, such as ultra-high performance liquid chromatography-high resolution mass spectrometry (UHPLC-HRMS) and triple quadrupole mass spectrometry (TQMS) to compare the plasma metabolomics differences of 15 celiac disease patients in Northwest China with 15 healthy volunteers and 30 inflammatory bowel disease patients. We also investigated the dietary and nutritional status of research participants and used Linear mixed effects calibration to perform factor correction on metabolomics results. Informed consent was obtained from all participants, and the study was approved by the Ethics Committee at Affiliated Hospital of Nanjing University of Chinese Medicine(2019NL-085-02) and the ethics committee of the people's Hospital of Xinjiang Uygur Autonomous Region (KY20220311067).

Results: The average age of CeD patients is 43.9 years old, 13 female and 2 male. The average of tissue transglutaminase antibody, tTG is 1792 (CU). Under the condition of false discovery rate (FDR) < 0.05, variable importance projection (VIP) > 1.0, and fold change (FC) > 1.5 or < 2/3, we found 330 plasma differential metabolites with 200 positive ions and 130 negative ions in celiac disease when compared with healthy control. Then, with area under the curve (AUC) ≥ 0.85 and FC ≥ 2.5 or ≤ 0.4, 146 potential biomarkers were identified, such as, fructose-6-phosphate(F6P), D-Erythrose 4-phosphate, which belongs to the pentose phosphate pathway (the abundance decreased), and succinic acid, Citric acid, isocitric acid, which belongs to the citric acid cycle (the abundance increased). Other fatty acid metabolites, such as 13-Hydroxyoctadecadienoic acid (13-HODE) were also involved. Amino acid derivatives, such as phenylacetyl-L-glutamine were part of candidate biomarkers. D-ribose 1,5-bisphosphate, a compound which is not a naturally occurring metabolite in human was found as a significant differentiate substance in our study. The results of comparison between celiac disease and inflammatory bowel disease patients were quite similar to the results compared with healthy controls.

Table 1. Parts of potential biomarkers for Celiac disease when compared with healthy controls.

Conclusion: Metabonomics findings support celiac disease as multifactors disorder. The abundance of the main metabolites in the pentose phosphate pathway decreases and the abundance of the main metabolites in the citric acid cycle increases in the Chinese patients with celiac disease. Changes in central carbon energy metabolism are the main aspects of celiac disease. Environmental factors, which might be part of the human exposome, also could contribute for the development of CeD. Specific mechanism needs further exploration.

MODELLING ENTEROVIRUS-INDUCED PREDISPOSITION TO CELIAC DISEASE: SINGLE-CELL TRANSCRIPTOMIC ANALYSIS OF COXSACKIE B VIRUS-INFECTED ORGANOID

H. Hien Le¹, V. Dotsenko¹, A. Sioofy Khojine², J. Laiho², H. Hyöty², K. Viiri¹

Introduction: Celiac disease (CeD) is an autoimmune disorder influenced by genetic and environmental factors, primarily triggered by dietary gluten in genetically predisposed individuals. Enterovirus infections, as an additional environmental factor, have been linked to the development of CeD. We aimed to model molecular mechanisms on how enterovirus infection predisposes to CeD.

Aims & Methods: We used single-cell RNA sequencing (scRNAseq) and one enterovirus, coxsackievirus B1 (CVB1) infection in human intestinal

organoids as a model to explore the comprehensive transcriptional response of the intestinal epithelium damage. A total of 3940 single epithelial cells were evaluated for lineage biomarkers, differentially regulated genes, receptors, inflammation- and antiviral responses.

Results: CVB1 infection induced innate immune antiviral response in the intestinal epithelium. Single cell transcriptional profiling of the epithelium indicated that the main response to CVB1 infection expectedly occurs through interferon (IFN) related pathways. CVB1 induced innate IFN-2/3 and IFN- β 1 and, surprisingly, also triggered high expression of transglutaminase 2 (TG2) in human intestinal organoids.

Conclusion: Our work provides mechanistic, single-cell level, detail how CVB infection can poise to gluten-induced inflammatory damage in CeD. We hypothesise that CVB infection-induced surge of innate interferons in the intestinal epithelium can predispose to CeD by inducing the TG2 gene expression in specific epithelial cells and accelerate gliadin deamidation, step necessary to CeD pathogenesis.

In addition, our pathway analyses provide insights as to how the intestinal epithelium responds to the enterovirus infection and can possibly reveal novel anti-viral drug targets to inhibit virus-host interaction in endeavors to prevent CeD.

PRE-NATAL EXPOSURE TO ANTIBIOTICS IS ASSOCIATED WITH INCREASED PREVALENCE OF CELIAC DISEASE

R. Nassar¹, E. Brav¹, G. Howard¹, G. Ling¹, B. Yerushalmi¹

Contact E-Mail Address: raouf.n@gmail.com

Introduction: Celiac disease (CD) is an immune-mediated enteropathy triggered by the ingestion of gluten-containing grains in genetically susceptible individuals. The prevalence of CD has increased dramatically over the last decade, with a prevalence of 1%-3%. Several risk factors for CD are reported, including genetic, nutritional, infections, mode of delivery, and exposure to post-natal antibiotics.

Aims & Methods: The aim of the study is to examine the association between prenatal exposure to antibiotics and CD. In a retrospective cohort study, we enrolled all the children born between 2000 and 2023 to mothers who belong to "Clalit" HMO and compared the prevalence of the CD between the children whose mothers purchased one or more antibiotics during the pregnancy and the children who didn't.

Results: A total of 658,899 children have met the inclusion criteria; 5,706 children were diagnosed with CD during the study years, with a prevalence of 0.86:100. The prevalence of CD among the children whose mothers received one or more antibiotic treatments during pregnancy was higher compared to those who didn't (0.9:100 vs. 0.8:100, p-value=0.003). A multivariable regression including the mother's age, mode of delivery, and history of CD of the mother showed RR of 1.07 (95%CI 1.01-1.13).

Conclusion: Unlike previous studies, our study showed a positive association between prenatal exposure to antibiotics and CD.

This association can be explained by several theories, including the effect of antibiotics on the maternal microbiome and the stimulation of the immune system. Further studies are warranted to explore the mechanism of this association.

Introduction: There is an unmet need for adjunctive therapies for patients with celiac disease (CeD) who experience inadequate disease control while maintaining a gluten-free diet (GFD). The optimal trial design to assess CeD treatment efficacy is unclear and increased adherence to a GFD during trials may improve disease control. We assessed symptom severity changes during the screening and run-in periods (no treatment) of two phase 2b CeD trials, one using simulated inadvertent gluten exposure (SIGE) and one without.

Aims & Methods: In two concurrent ongoing phase 2 CeD trials (NCT05353985 and EudraCT2020-004612-97) daily gastrointestinal (GI) symptom severity was measured using the Celiac Disease Symptom Diary 2.1® during the screening and run-in periods (4 weeks each in NCT05353985; 6 weeks and 5 weeks, respectively in EudraCT2020-004612-97) before any treatment administration. In both trials, eligible patients had biopsy-confirmed CeD and were experiencing CeD-related symptoms and enteropathy despite following a GFD. NCT05353985 included food bars containing ~500 mg gluten, consumed 3-times weekly after Week 2, for 2 weeks during the run-in period (post randomization). EudraCT2020-004612-97 did not include gluten exposure. Mean GI symptom severity scores were calculated each week during the screening and run-in periods.

Results: From the start of the screening period through to the end of the run-in period, mean GI symptom severity scores improved significantly in EudraCT2020-004612-97 (0.96 at Week 1 of screening, and 0.75 at Week 5 of run-in) whereas changes were non-significant in NCT05353985 (0.96 at Week 1 of screening and 0.92 at Week 4 of run-in).

Conclusion: Clinical trial participation may result in an improvement in CeD-related GI symptoms due to better GFD adherence. Administration of SIGE can minimize such trial effects and does not worsen symptoms in patients with CeD.

INVESTIGATION OF BODY COMPOSITION PARAMETERS IN PATIENTS WITH CELIAC DISEASE ON A GLUTEN-FREE DIET. PROSPECTIVE, MULTICENTER, CASE-CONTROL STUDY (ARCTIC STUDY)

M.Z. Peresztegi¹, Z. Vereczkei², Z. Sipos³, N. Farkas^{3,3}, B. Máth⁴, K. Lemes⁵, Z. Lenart⁵, V. Papp⁶, E. Dakó⁷, S. Dakó⁶, J. Bajor⁸

Contact E-Mail Address: peresztegzis@gmail.com

Introduction: Body composition parameters in patients with celiac disease differ from the normal population, and in some cases, they do not completely normalize even with a gluten-free diet. Despite weight gain on the diet, the change in body composition is generally unfavorable (less increase in fat-free body mass, significantly higher increase in fat content). One reason for this is improved absorption, but the high calorie, sugar,

and fat content of the gluten-free diet can also lead to undesirable weight gain and unfavorable metabolic changes (dyslipidemia, fatty liver, insulin resistance) without dietary control.

Aims & Methods: In our prospective multicenter, case-control study (ARCTIC study), we examined body composition parameters and blood lipid levels of patients with celiac disease who had been on a gluten-free diet for at least 1 year and compared them to those of healthy control individuals.

Patients from three university centers with celiac disease participated in the study. Body composition analysis was performed using an Inbody 770 device, measuring the following parameters: body mass index (BMI), waist-hip ratio, Inbody score, Skeletal muscle mass (SMM), Percent body fat (PBF), Visceral fat area (VFA). Blood lipids including total cholesterol, LDL, and triglyceride levels were measured. Abdominal ultrasound was performed to assess the degree of hepatic steatosis. Fischer's exact test and Chi-Square test were used for categorical variables, and the Welch Two Sample t-test was used to assess continuous variables. A p-value less than 0.05 is considered statistically significant.

Results: 97 patients with celiac disease (78 female, 19 male) and 47 (40 female, 7 male) control individuals were included. The mean age of patients with celiac disease (36.2 years) was slightly higher than that of controls (32.5 years), but the difference was not significant. The mean waist and hip circumference were higher in patients with celiac disease but did not reach the significance threshold ($p=0.051$ and $p=0.10$). Among the body composition parameters, higher mean BMI, Skeletal muscle mass, Percent body fat, Visceral fat area, and lower Inbody score were observed, but the differences were not significant ($p=0.31$, 0.16, 0.72, 0.39, 0.62). Based on BMI, 9.3% of celiac patients were underweight, 54.7% had normal weight, 18.5% were overweight, and 17.5% were obese. These proportions for controls were: 8.5%, 66%, 19%, 6.5%. The mean total cholesterol level was lower in patients with celiac disease ($p=0.043$), while the mean triglyceride level was higher ($p=0.85$). We found significantly more cases of hepatic steatosis in celiac patients than in controls ($p=0.012$). Among them, 83% met the Metabolic Dysfunction-Associated Liver Disease (MASLD) criteria, while 60% of controls with hepatic steatosis did.

Conclusion: The body composition parameters of celiac patients on a gluten-free diet are less favorable compared to control cases, albeit not significantly. Our data suggest that for most of these patients, the problem is not caused by malabsorption and malnutrition. Preventing cardiovascular and metabolic complications poses a new challenge in patient care.

Introduction: This study assessed typical symptoms (abdominal pain, bloating, diarrhoea, nausea, tiredness) in patients with celiac disease (CeD) following a gluten-free diet (GFD) and evaluated the association between symptom severity and quality of life (QoL) to address limited data in this area.

Aims & Methods: In the Virtual Celiac Symptoms Study (NCT05309330), patients reported daily symptoms using the Celiac Disease Symptom Diary 2.1[®] (CDS 2.1[®]) over 12 weeks and completed patient-reported outcome measures (PROMs), with 7-day look-back, at specified timepoints, including the Impact of Celiac Disease Symptoms Questionnaire (ICDSQ) and the Patient Global Impression of Severity (PGI-S) measure. Spearman's correlation coefficient (SCC) and generalized linear regression evaluated associations between symptom severity and QoL PROM scores and mean differences were adjusted for key demographics.

Results: In total, 480 participants completed the study (mean [standard deviation] age: 31 [15] years, 81.7% female, 93.8% White). For all CeD symptoms measured, there was a positive linear association between CDS 2.1[®] symptom severity and PROM scores ($p < 0.001$). The SCC between symptom severity and PROMs was 0.45–0.62 (PGI-S) and 0.33–0.56 (ICDSQ). The strongest correlations between gastrointestinal symptom severity (abdominal pain, bloating, diarrhoea, and nausea) and PROMs were between PGI-S score and abdominal pain (SCC: 0.62) and bloating (SCC: 0.59). Patients with severe/very severe abdominal pain versus none had mean (95% confidence interval [CI]) 63.1% (53.2–73.6) and 217.5% (165.1–280.2) greater PGI-S and ICDSQ scores, respectively.

Conclusion: The results indicate that higher symptom severity is strongly associated with worse QoL in patients with CeD following a GFD and that CDS 2.1[®] assesses patient-relevant symptom severity in CeD.

Contact E-Mail Address: calvin.johnson@nhs.net

Introduction: Machine learning algorithms (MLA) trained on capsule endoscopy (CE) images have shown high accuracy in detecting signs of villous atrophy in patients with coeliac disease. However, using MLA to quantify coeliac disease extent and the proportion of small bowel affected has not been studied.

Aims & Methods: We analysed CE videos of adult patients (≥ 18 years) with biopsy-proven coeliac disease from a large prospectively maintained database. Demographic, clinical, and biochemical data were collected for all patients. The extent of coeliac disease and the proportion of small bowel affected were calculated for each video by an expert human reader and by a trained MLA. The consistency of agreement between the expert human and the MLA was estimated by intraclass correlation coefficients (ICCs) using a two-way mixed-effects model.

Results: CE videos of 75 patients with CD (median age 59 years [IQR 41.5–68 years], 60% female) were included. The median gastric passage time and small bowel transit time were 16 (IQR 98–50.5) and 277 (IQR 217.5–252) minutes, respectively. Macroscopic features of CD, including scalloping, fissuring, mosaicism, nodularity, were identified beyond the first tertile in 34.7% of patients (extensive disease). The overall agreement between the expert human and MLA for the proportion of small bowel affected was good (ICC 0.799, 95% CI 0.572–0.893). Patients with extensive small bowel CD were significantly more likely to have anaemia or ferritin deficiency than those with proximal disease ($p < 0.01$ and 0.026 respectively).

Conclusion: Trained MLA can accurately quantify the extent of coeliac disease and the proportion of small bowel involvement on CE, showing a good agreement with expert human assessment. This machine learning quantification of coeliac disease extent allows closer monitoring for nutritional deficiencies associated with extensive disease and provides an objective and standardised endpoint on response to therapy in clinical trials. Larger training and validation datasets are required to optimise the performance of the MLA.

Disclosure: Nothing to disclose.

Introduction: Patients with recently diagnosed celiac disease (CD), usually present with upper gastrointestinal manifestations, including bloating, abdominal pain and chronic diarrhea or constipation, thus adopting several restrictive tendencies, apart from the standard-of-care gluten-free diet (GFD). Avoidant/restrictive food intake disorder (ARFID) is a newly established eating disorder affecting primarily children, but with emerging evidence among adults. We aimed to examine the prevalence of ARFID and the eating attitude among adults with recently diagnosed celiac disease.

Aims & Methods: In a prospectively maintained cohort of adult patients with a recent diagnosis of celiac disease, we evaluated eating habits of patients with a recent diagnosis of CD who were under GFD through the Eating Attitudes Test (EAT-26) and the prevalence of ARFID through nine item avoidant/restrictive food intake disorder screen (NIAS), containing three subscales (picky eating, appetite, fear).

Results: A total of 28 patients were enrolled [mean age 37.07 years old (IQR 23.47), 22 females (78.6%)], with a mean body mass index (BMI) of 23.7kg/m² (mean weight 65.2 kg and mean height 1,70m). A self-reported suspected food intake disorder had been reported by 35.7% of patients, while 21.4% were referred to a specialized mental care professional and 7.1% had been diagnosed by a non-specific food disorder in the past 6 months. Physical activity was limited or absent in 78.6% of enrolled patients.

Both EAT-26 and NIAS questionnaires displayed acceptable values on reliability analysis (Cronbach's alpha score 0.618 and 0.658 respectively). A total of 14% (4 out of 28 patients, 100% females) met criteria for ARFID, with a mean score of 42 points on the total scale of NIAS. Patients with ARFID reported that other people think that they are too thin ($p=0.004$) and felt external pressure from others to eat ($p<0.001$).

Females reported to push significantly themselves to eat regularly or large amounts of food on a daily basis ($p=0.04$), significantly consumed more time and thought to food ($p<0.001$), enjoyed trying new rich foods ($p=0.02$) and suffered from eating binges ($p=0.003$) compared to males. However, there were no differences between BMI, the self-reported suspected food disorder and the diagnosed mental health conditions. Additionally, CD patients with suspected and diagnosed food disorder scored similarly to all given questionnaires.

Conclusion: In a small sample of patients with recently diagnosed CD, ARFID may present up to 15% and contribute to persistent symptomatology and food restrictive attitude, despite being on GFD. Although females were found to be more susceptible to ARFID, by reporting more binge eating symptomatology and external factors exerting pressure, no significant differences were found on age, gender, BMI in our cohort.

Disclosure: Nothing to disclose.

PREVALENCE OF PATHOLOGY IN PATIENTS WITH IRON DEFICIENCY ANAEMIA

P. Oka¹, M.G. Shiha¹, A. Finta², L. Madácsy², T.L.M. Wong³, Y. Yuan³, J.Y.W. Lau³, R. Sidhu⁴, M. McAlindon¹

¹Sheffield Teaching Hospitals NHS foundation trust, Gastroenterology, Sheffield, United Kingdom, ²Endo-Kapszula Ltd., Endoscopy Unit, Szekesfehervar, Hungary, ³Chinese University of Hong Kong, Hong Kong, Hong Kong, ⁴Sheffield Teaching Hospitals NHS foundation trust, Academic Dept of Gastroenterology, Sheffield, United Kingdom

Contact E-Mail Address: oka.priya@gmail.com

Introduction: Current guidelines suggest upper and lower GI endoscopy to investigate iron deficiency anaemia (IDA) because of a perceived low risk of small bowel pathology. This is the first study to investigate the entire gastrointestinal tract to localise lesions suspected of causing blood loss in patients with IDA.

Aims & Methods: Patients referred to three centres (Sheffield, Hong Kong and Szekesfehervar, Hungary) for the investigation of IDA underwent small bowel (SB) capsule endoscopy (Navicam, AnX Robotica, Plano, US) a week prior to upper and lower gastrointestinal endoscopy. All lesions were described using terms selected from a predetermined diagnostic list and according to the perceived likelihood of bleeding (P0: unlikely; P1: suspected; P2: likely. Saurin et al., Endoscopy 2003).

Results: Assuming a true prevalence of small bowel lesions of 10% in patients with IDA, a sample size required to have 80% power of getting a 95% confidence interval for the prevalence no wider than 10 percentage points is 160 patients. 164 patients (median age 61 years (IQR 48.2-72); 50.6% male) had a median haemoglobin of 102.0 g/L (IQR 90.0-116.0), ferritin 11(IQR 7- 18). Completion rates for gastroscopy, colonoscopy and capsule endoscopy were 99.3%, 95.7% and 85.9% respectively. Diagnostic yield of P1/P2 lesions by SB capsule (49.3%) was higher than gastroscopy (25.7%) and colonoscopy (26.8%); $p<0.0001$. Four patients had fresh blood seen on capsule the source of which was unclear. Four additional patients were given new diagnoses of coeliac disease at capsule endoscopy which was subsequently confirmed following duodenal biopsy. All lesions were defined by a three-person expert panel review by consensus with a 99.1% agreement.

Gastroscopy pathology	Small bowel (SB) pathology	Colonoscopy pathology
Oesophageal erosions	4	SB angiodysplasia 50
Oesophageal ulcers	4	Small bowel ulcers 18
Oesophageal Varices	2	Ulcerated stenosis 3
Gastric tumour	2	Eroded SB polyp 2
Gastric ulcers	5	Small bowel erosions 21
Gastric angiodysplasia	1	Colonic angiodysplasia 3
Gastric erosions	16	Colorectal cancer 9
Eroded gastric polyp	2	Friable colonic polyps 3
GAVE	3	Haemorrhoids 16
PHG	1	
Duodenal adenoma	1	
Duodenal ulcer	2	
Duodenal erosions	3	
Duodenal angiodysplasia	1	

Table-1: Number of patients with P1/P2 pathology identified at gastroscopy, SB capsule and colonoscopy.

Conclusion: Pathology suspected of, or likely to be, causing blood loss in patients with IDA appears to be commoner in the small bowel than the proximal GI tract or colon. Small bowel examination should be performed routinely to maximise diagnostic yield.

Disclosure: Capsules for the study were provided by AnX robotica.

Introduction: Eosinophilic esophagitis (EoE) presents with varying histologic extents, yet the impact of comorbidities on eosinophilic distribution and the implications on disease progression and treatment response remains poorly understood.^{1,2} This study aimed to investigate the prevalence of different EoE extents and their impact on disease progression and treatment response within a multicenter cohort.
Aims & Methods: Clinical, endoscopic, and histologic data from adult EoE patients actively followed up at four Italian referral centers from October 2022 to October 2023 were retrospectively collected. The primary endpoint was to assess the prevalence of different EoE histologic extents (proximal, distal, diffuse) based on the presence of a pathological eosinophilic infiltrate (³15 Eo/HPF) and evaluate their association with comorbidities (atopic diseases, gastroesophageal reflux disease), clinical characteristics, endoscopic features. The secondary objective was to compare treatment responses among different histologic extents of EoE.
Results: 149 patients were included (median age: 37 years [IQR 25-51], 38.2% males). Proximal EoE was observed in 8.1% (12/149), distal EoE in 27.5% (41/149), and diffuse EoE in 64.4% (96/149) of patients. In proximal-EoE, male patients were significantly more prevalent (91.7% vs. 68.3% distal-EoE vs. 55.5% diffuse-EoE, P=0.03). No significant differences were found in the rate of autoimmune comorbidities (8.3%, 14.6% distal-EoE, 10.4% diffuse-EoE; P=0.8). Only allergic rhinitis was significantly more prevalent in the distal and diffuse-EoE groups compared to the proximal group (33.3% vs. 72.5% vs. 61.5%, P=0.049). The prevalence of asthma, atopic dermatitis, oral allergy syndrome, and gastroesophageal reflux disease was similar among the three EoE extent groups. Endoscopic inflammatory features at diagnosis were significantly more prevalent in the proximal-EoE group, compared to the distal and diffuse-EoE groups (91.7% vs 53.8% vs 66%; P=0.05). Endoscopic fibrotic features at diagnosis were similar between all the groups (proximal-EoE 50%, distal 42.5%, and diffuse-EoE 51.1%; P=0.6) The clinical response after first-line therapy was comparable in all groups (75.0%, 70.7%, and 69.8%, P=0.93) and proton pump inhibitors were the most frequently prescribed therapy (77.8%). The endoscopic fibrotic remission rate after first-line therapy was higher in the proximal-EoE compared to the distal and diffuse-EoE groups (100.0% vs. 35.7% vs. 13.8%, P=0.0001).

	Overall N=149	Proximal-EoE N=12	Distal-EoE N=41	Diffuse-EoE N=96	P
Age, years, median (IQR)	37 (25-51)	38 (23-69.5)	39 (25-47.5)	37 (26-51)	0.54
Male sex, n (%)	57 (38.2)	11 (91.7)	28 (68.3)	53 (55.2)	0.03
Autoimmune disorders, n (%)	17 (11.4)	1 (8.3)	6 (14.6)	10 (10.4)	0.84
Asthma, n (%)	41 (27.8)	6 (50.0)	9 (22.5)	26 (27.1)	0.17
Atopic dermatitis, n (%)	13 (8.8)	1 (8.3)	4 (10.0)	8 (8.3)	0.90
Allergic rhinitis, n (%)	92 (62.2)	4 (33.3)	29 (72.5)	59 (61.5)	0.049
Oral allergy, n (%)	15(10.1)	0 (0.0)	3 (7.5)	12 (12.5)	0.51
Proven GERD at diagnosis, n (%)	21 (14.3)	1/11 (9.1)	3 (7.5)	17 (17.7)	0.26

Table 1. Demographics and clinical characteristics
EoE, eosinophilic esophagitis; IQR, interquartile range.

Conclusion: In adult patients with EoE, an increasing proximal-to-distal gradient of esophageal eosinophilic infiltrate was observed. There was no clear correlation between the histologic extent of EoE and comorbidities, development of fibrosis, and response to treatment.

THE TIME TO EOSINOPHILIC OESOPHAGITIS DIAGNOSIS FOR PATIENTS PRESENTING WITH UPPER GASTROINTESTINAL SYMPTOMS IN PRIMARY AND SECONDARY CARE

N. Umar¹, C. Turnbull², R. Jazrawi³
¹Sandwell and West Birmingham Hospitals NHS Trust, Gastroenterology, West Bromwich, United Kingdom, ²Dr. Falk Pharma GmbH, Bourne End, United Kingdom, ³Dr. Falk Pharma UK Ltd. Medical Department., Bucks, United Kingdom

Contact E-Mail Address: nosheen.umar@nhs.net
Introduction: Patients with eosinophilic oesophagitis often experience diagnostic delays. Untreated eosinophilic oesophagitis may result in fibrosis and stricture formation, leading to morbidity and impaired quality of life. Early diagnosis and treatment can potentially prevent these outcomes and reduce emergency admissions with food bolus obstruction. The reasons for these delays have not been examined in primary care previously. This study quantifies the time to eosinophilic oesophagitis diagnosis and examines factors associated with diagnostic delays.
Aims & Methods: A retrospective cohort study of incident eosinophilic oesophagitis patients between 1st Jan 2006 and 31st Dec 2022 was undertaken using Clinical Practice Research Datalink (CPRD AURUM) linked to hospital admission data in Hospital Episode Statistics. Patients were followed from first proton pump inhibitor (PPI) prescription or presentation with eosinophilic oesophagitis related symptoms (food bolus obstruction or dysphagia) identified from SNOMED CT codes for primary care and ICD-10 codes for secondary care to diagnosis. The association between patient level factors and time to eosinophilic oesophagitis diagnosis was examined using a Robust Poisson regression model.
Results: 2300 eosinophilic oesophagitis patients were studied (67.7% male; age 38 (IQR 30-49)). Median time to diagnosis was 3.6 years (IQR 0.5-8.7). 80.7% patients had a PPI prescription record in primary care prior to eosinophilic oesophagitis diagnosis with a time to eosinophilic oesophagitis diagnosis of 4.9 years (IQR 1.5- 9.7). Factors associated with more than 3 years to diagnosis included: female sex (adjusted risk ratio

1.18, 95% CI 1.10-1.27); smoking (1.11, 1.01-1.23); compared with baseline of elective endoscopy, urgent endoscopy for dysphagia (1.35, 1.18-1.54), urgent endoscopy for food bolus obstruction (1.26, 1.13-1.41), dysphagia presentation in primary care (1.16, 1.08-1.25), food bolus obstruction presentation in primary care (1.11, 1.00-1.23) and PPI prescription in primary care (3.08, 2.58-3.67). 77% of patients had PPI treatment prescribed after eosinophilic oesophagitis diagnosis. 21% patients with no history of asthma or chronic obstructive pulmonary disease were prescribed a steroid inhaler (presumably swallowed) after eosinophilic oesophagitis diagnosis.

Conclusion: Longer time to eosinophilic oesophagitis diagnosis was associated with being female, smoking, food bolus obstruction and dysphagia presentations in primary or secondary care and particularly PPI prescriptions in primary care.

MISDIAGNOSIS IS COMMON ON THE PATH TO EOSINOPHILIC ESOPHAGITIS

L. Biedermann¹, K. Dave², C. Zema³, D. Mascia⁴, T. Pennant⁴, J.W. Chang⁵

¹Department of Gastroenterology and Hepatology, Universitäts Spital Zürich, Zürich, Switzerland, ²Bristol Myers Squibb, Uxbridge, United Kingdom, ³Bristol Myers Squibb, Princeton, NJ, United States of America, ⁴Adelphi Real World, Bollington, United Kingdom, ⁵Division of Gastroenterology, Department of Internal Medicine, University of Michigan, Ann Arbor, MI, United States of America

Contact E-Mail Address: Luc.Biedermann@usz.ch

Introduction: Patients with eosinophilic esophagitis (EoE) commonly face diagnostic delays, often due to misdiagnosis of conditions with similar symptoms such as gastroesophageal reflux disease (GERD).¹⁻³ Diagnostic delay in EoE has been associated with stricture formation, food impaction, persistent symptoms with impaired quality of life, and potentially a decrease in response to treatment.

Aims & Methods: This study examined the path from first symptoms to EoE diagnosis from both physician and patient perspectives and the impact of misdiagnosis. Data were from the Adelphi EoE Disease Specific Programme™ (DSP), a real-world, cross-sectional survey of physicians and their patients with confirmed diagnosis of EoE in the US, UK, and EU (France, Germany, Italy, Spain) from July to December 2023, including clinical data abstracted from medical records.⁴

Physicians reported if patients had been misdiagnosed prior to EoE diagnosis and the timing of key milestones, such as first symptoms, first medical consultation, and referral. Patients also reported timings of key milestones. We completed a descriptive analysis and presented results for the subset of patients who completed the survey and had clinical data abstracted.

Results: Physicians (n=190; 73% gastroenterologists, 18% allergists, 4% internal medicine, 4% pediatric gastroenterologists, 1% pediatric allergists) abstracted data on 1141 patients with EoE (93% adults, 89% White), of which 285 also completed a survey (25% response rate). For 967 patients, physicians assessed if the patient was previously misdiagnosed; 28% (n=272) were misdiagnosed, and the majority (81%) were misdiagnosed with GERD prior to the EoE diagnosis. Physicians reported that those who were misdiagnosed had a longer time from (1) first documented symptoms to patient's first medical consultation (mean days [SD]: 368.7 [671.0] vs 175.6 [611.8]) and (2) first consultation to EoE diagnosis (mean days [SD]: 332.3 [503.2] vs 78.9 [149.9]) when compared with pa-

tients who were not misdiagnosed (n=695). Misdiagnosed patients themselves also reported longer time from first symptoms to first medical consultation (mean days [SD]: 622.2 [1161.3] vs 327.1 [1154.2]) (Table).

Conclusion: Diagnostic delay is a known challenge in the management and care of EoE. Not only is clinical presentation underrecognized, but patients with EoE are commonly misdiagnosed, often with GERD, and experience prolonged diagnostic delay. Patients with a physician-confirmed misdiagnosis prior to their EoE diagnosis had longer time from their first symptoms to diagnosis due to both patient delay in seeking medical care and diagnostic delay. These findings highlight the significant unmet need for physician and patient education regarding EoE symptoms in order to facilitate timely diagnosis of EoE, which could aid in appropriate treatment strategies and improve both short- and long-term outcomes for patients with EoE.

Contact E-Mail Address: vittoriostorer95@gmail.com

Introduction: Eosinophilic esophagitis (EoE) is a chronic, immune-mediated oesophageal disease that is showing a skyrocketing increase of new diagnoses in last two decades. Although tons of papers have been published clarifying several aspects of this disease, most of the evidences come from high volume – referral centres that may be not representative of the whole EoE population. In fact, little is known about demographic and clinical features as well as treatment outcomes of patients managed in community hospitals.

Aims & Methods: Between January 2021 and June 2023, we prospectively enrolled all EoE patients evaluated for the first time at two different centres: 1) a high-volume tertiary-care centre, the University Hospital of Padua (PH), that represent a national referral centre; 2) a low-volume community hospital, the hospital of Feltre (FH), with a catchment area of about 25,000 people, both located in the North-East of Italy. The diagnosis of EoE was made according to the latest international guidelines. Endoscopic features were assessed according to EREFS score (0-8 points). Histological remission was considered for eosinophilic peak <15 eos/HPF. The main goals of our study were to compare the cohorts of EoE patients from a community and a tertiary care centre in terms of demographic and clinical features as well as to assess differences in the rate of histological response to medical treatments.

Results: Overall, 210 patients were consecutively enrolled, 177 (84.3%) in the tertiary centre (PH) and 33 (15.7%) in the community one (FH). We

did not find any significant difference between PH cohort and FH patients regarding age (34.80 vs 38.24 years, $p=0.193$), male prevalence (79.1% vs 72.7%, $p=0.491$), body mass index (22.55 vs 22.63, $p=0.906$), prevalence of non-atopic comorbidities (35.6% vs 21.2%, $p=0.158$), diagnostic delay (3.35 vs 2.62 years, $p=0.682$). A not significant trend in higher EREFS score values was found in PH (3.3 vs 2.7, $p=0.062$). There was a significant difference regarding the number of patients that were evaluated for a second opinion (77% vs 15%, $p<0.001$) and the prevalence of atopic comorbidities (68.9% vs 42.4%, $p=0.008$), both higher in PH court.

Regarding medical treatments 184 patients were treated with PPI (157, 88.7% at PH and 27, 81.8% at FH, $p=0.219$). There was a significant difference in the rate of PPI response comparing PH and FH patients (29.94% vs. 51.85%, $p=0.044$). No differences in terms of rate of responsiveness regarding swallowed flutotide puffer (44% vs 36%, $p=0.295$) and orodispersible budesonide (50.9% vs 61.5%, $p=0.564$).

Conclusion: This study elucidated several significant aspects regarding EoE. Firstly, it revealed that EoE patients treated in peripheral hospitals may exhibit a milder phenotype, characterized by less severe endoscopic features and fewer atopic comorbidities. Conversely, more complex cases tend to be referred to specialised centres, often seeking for a second opinion. Accordingly, the rate of PPIs responsiveness was found to be higher in community hospitals and, indeed, they still hold a significant as effective therapeutic option for EoE patients. Given that most of the evidence come from high-volume referral centres, it is crucial to keep in mind these differences when assessing the wide spectrum of EoE patients. Although the need for new therapies is still a fact, the increasing prevalence of EoE also necessitates a thorough evaluation of the financial implications of these drugs.

Contact E-Mail Address: barchi.alberto@hsr.it

Introduction: Long-term maintenance treatment efficacy, safety and tolerability in eosinophilic esophagitis (EoE) is still partially understood. The aim of this study was to evaluate long-term outcomes of maintenance treatment for EoE with various drugs and dose regimens in real-world observational studies and randomized controlled trials (RCTs).

Aims & Methods: Systematic search was performed on Pubmed-MEDLINE, Embase and Cochrane Central Register of Controlled Trials from inception to October 2023. Studies reporting histologic success of maintenance therapy for EoE patients > 48 weeks, following 8-12 weeks of induction therapy with the same drug were included. Primary outcome was pooled histologic success (defined as < 15 eosinophils/HPF) at the end of follow-up for both study designs. Risk Difference (RD) or Odds Ratio (ORs) for histological success of maintenance therapy versus placebo (PBO) (for RCTs) and versus induction (for both study designs), pooled drug-related

adverse events (AEs), endoscopic and clinical success rates were assessed as secondary outcomes. Random effects model metanalyses were performed. A-priori sub-group analyses were performed to address substantial inter-study heterogeneity (measured with I² statistic).

Results: From 3,916 full articles, 23 articles matched inclusion criteria (17 observational studies and 6 RCTs), 7 with pediatric patients only. Overall, 1,923 patients (M 70.1%; mean age 29.8±12.6 years). Mean follow-up time was 78.4 weeks. Budesonide (either oro-dispersible or viscous suspension) was administered in 7 studies (including 2 RCTs), PPI in 6 studies (all observational, 4 pediatric), Fluticasone in 5 studies (including 1 RCT with 4 cohorts), Dupilumab in 2 RCTs and Cendakimab in 1 RCT. Pooled rate of long-term histologic success for RCTs was 83% (95% CI, 77%-89%; I² 73.1%), while for observational studies attested at 53% (95% CI, 42%-65%; I² 93.5%) at a median follow-up of 97.8 weeks. Maintenance therapy in RCTs showed a RD of -0.71 (95% CI; -0.92-0.50; p<0.01; I² 88.9%) versus PBO, while a RD of -0.06 (95% CI; -0.11-0.01; p<0.016; I² 23.1%) compared with induction. Observational studies showed a non-significant (p=0.38) Odds Ratio (OR) of 1.37 (95% CI, 0.66-2.85; I² 81.3%) of losing histologic success during therapy de-escalation. Pooled clinical success among RCTs attested at 61% (95% CI, 51%-75%; I² 71.3%), comparable with observational studies (60% [95% CI, 42%-77%; I² 97.3%]). Biological therapy (either Dupilumab or Cendakimab at various regimens) ranked first for pooled histologic success rate among RCTs with 79% (95% CI; 71%-87%; I² 54.9%). In observational studies, PPI with histologic success of 64% (95% CI, 50%-78%; I² 88.7%) and clinical success of 79% (95% CI; 66%-93%; I² 85.2%) ranked first. Pooled rate of AEs among RCTs attested at 34% (95% CI; 22%-45%; I² 93.2%), with a pooled candidiasis infection rate of 6% (95% CI; 2%-10%; I² 61.9%), comparable with pooled AEs among observational studies (5% [95% CI, 2%-7%; I² 66.7%]). Pooled therapy discontinuation rate was 0.14 (95% CI, 0.073-0.210, I² 94.49%) in real-world data.

Conclusion: This is the first meta-analysis on efficacy and safety of long-term maintenance treatment (median 78 weeks) for EoE. All treatments showed good efficacy in maintaining long-term histological remission without clear disadvantage in de-escalating therapy during maintenance in real-world data. Biological therapies resulted the most effective in RCTs, while PPIs in observational studies. Low adverse events rates and low therapy discontinuation rates confirm long-term treatment is well tolerated.

Introduction: Initial first-line therapy for NEH and EPS are often PPIs, that are not indicated for long-term use and should be considered for de-prescribing (AGA CPU, Gastro 2022;162:13341). However, discontinuation of prolonged PPI therapy is followed by rebound acid hypersecretion (RAHS) and often by symptom recurrence. Antacids, alginates, and mucosal protective agents (MPA) are often used to counteract RAHS, but no controlled trials addressed the treatment phase of PPI deprescription in NEH and EPS

Aims & Methods: AIM to assess the efficacy of Poliprotect, an MPA made of natural substances, in the PPI deprescription phase of an RCT.

METHODS were reported in a published RCT (Corazzari et al *Am J Gastro* 2023;118:1024). Briefly, patients with a negative upper Gi endoscopy and complaining of heartburn NEH (n=81, F 63%) or Epigastric Pain/Burning (EPS) (n=45, F 67%) assumed omeprazole (20mg q.d) for 4 weeks. At PPI withdrawal they assumed Poliprotect made from *Aloe vera*, *Malva sylv.*, *Althea off.*, *limestone*, *nahcolite*, *Glycyrrhiza glabra*, *Matricaria recutita* (*Aboca*, *Sansepolcro*, Italy) 1.55 g tablet on demand for 4 weeks. VAS assessed daily symptom severity. A 50% VAS decrease from basal values defined a responder. Antacid was rescue medicine. Statistics with Wilcoxon rank sum test, and 2-sample test for equality of proportions, with continuity corrections.

Results: Demography and clinical baseline variables did not differ between NEH and EPS. During deprescription, poliprotect on-demand intake was of 2.36 (2.14) (M±SD) tablets/day. VAS score was [M (95%CI)] 25.6(21.0-

30.2) and 25.2(18.5-31.9) at the end of PPI treatment and 25.7(20.8-30.5) and 21.4(15.1-27.7) at the end of the deprescription in NEH and EPS, respectively. Rescue medicine consumption was 9.1±12.1 sachets and 8.7±10.8 during the 4-week PPI treatment and 11.1±12.2 and 20.2±23.4, (M±SD;n.s) during the 4 weeks of deprescribing in NEH and EPS patients, respectively. Responders' rate was 48% and 51.3% at the end of PPI treatment and 51.3% and 55% at the end of the deprescription in NEH and EPS, respectively. Of the entire sample, non-responders were 43% at the end of PPI treatment and 33.3% of them became responders at the end of the deprescribing phase. At the end of deprescription, GSRS GI symptom, and GIQLI QoL, items improved not significantly compared to those at the end of PPI treatment in both NEH and EPS. Treatment satisfaction was reported on OTE questionnaire by 82.8% and 85.7% at the end of PPI treatment and 81.3% and 95% at the end of the deprescription phase in NEH and EPS, respectively.

Conclusion: 1. At PPI deprescription, Poliprotect at the mean daily intake of 2.3 tablets appears to be equally effective in non-erosive Heartburn and Epigastric Pain Syndrome patients in

- counteracting the rebound acid hypersecretion effect
- maintaining the beneficial effect obtained with the previous PPI treatment
- reverting one-third of PPI non-responders to responders without any additional request for antacid rescue medicine.

2. Upper endoscopy-negative patients with heartburn and EPS appear to belong to the same clinical-therapeutic category as they cannot be distinguished for demography, accompanying gastrointestinal symptoms, gastrointestinal, physical, mental, and social items of quality of life, symptom severity, and response to treatment. The clinical use of the symptoms of heartburn, epigastric pain, or burning to differentiate patients with typical reflux-like symptoms from epigastric pain syndrome is not supported by the present data.

REAL WORLD EVIDENCE ON IMPACT OF GENERAL PRACTITIONER ALERTING MESSAGES ON NEW DGVS PPI DEPRESCRIBING GUIDELINES IN GERMAN PRIMARY CARE SETTINGS

K. Plehhova¹, J. Wray¹, M. Haering², P. Aluko¹, F. De Grey-Warter¹, E. Horvath¹, B. Kovacic¹, C. Coyle³

Contact E-Mail Address: kate.plehhova@reckitt.com

Introduction: The Deutsche Gastroenterologie, Verdauungs-und Stoffwechselkrankheiten (DGVS) guideline, issued in March 2023 in Germany, recommends limiting PPI therapy to 4-8 weeks' duration with aim of reducing unnecessary long-term use and potential adverse events, where an appropriate long-term indication is absent. Doses of long-term PPI should be regularly reviewed with the aim of prescribing minimum effective dose.

Aims & Methods: This study aims to assess the impact of targeted educational intervention using a General Practitioner (GP) alerting system at the point of prescription on recent PPI deprescribing guidelines. The study also sorts to identify patient prescribed PPIs while observing PPI prescription patterns pre and post guideline release.

A 12-month non-interventional real-world study was carried out leveraging GP alerting messages in the electronic medical record (EMR) containing non-commercial short messages on latest guidance, recommendations, and peer-reviewed publications around PPI deprescribing in the

management of Gastroesophageal reflux disease (GORD) and upper GI conditions. Baseline for this study was January to March 2023.

This study spans 54% of primary care practices in Germany with anonymised prescription data of GPs in 2400 private GP practices equipped with a GP information system. Data analysis was conducted in patients with ICD codes for uncomplicated reflux and diagnosed GORD to determine impact of this intervention on PPI prescription by comparing prescription numbers in terms of pack sizes, diagnosis codes and number of GPs reached monthly.

Results: Over the 12 months period, an average of 333 and 65 GPs were reached monthly for diagnosed GORD and uncomplicated reflux respectively. While there was variation in number of GPs reached monthly, analysis revealed a statistical significant difference in high numbers of PPI prescriptions without indicated diagnosis; mean difference of 15 GPs against those with diagnosis code (95%CI: 9.7-20.10; P<0.001) for uncomplicated reflux and 47 GPs for diagnosed GORD (95%CI: 19.7-74.3; P<0.0017). The ratio of patients with an ICD code per GP reached ranged from 0.34 to 0.47 for uncomplicated reflux and diagnosed GORD indicating that less than half of the patients per physician had documented diagnosis justifying PPI use. This highlights significant gap in guideline adherence. However, for diagnosed GORD, percentage of patients with diagnosis rose by approximately 10% from Q1 to Q4.

An analysis of the data also showed consistent large pack sizes being prescribed for both uncomplicated Reflux (ICD12) and Diagnosed GORD (ICD K21.0 and K21.9). For uncomplicated reflux, it was found that 86% of prescriptions after the intervention were for >3 months while uncomplicated reflux rose to 100%. This is consistent with the findings of Plehhova 2023¹, which found that between 2020 to 2021, more than 60% of PPI prescriptions were for > 3 months and Rückert-Eheberg 2022 which described high proportions of off-label use in Bavaria². This study also found that patients with diagnosed GORD and with uncomplicated reflux were often prescribed doses larger than 20mg, both before and after the messaging intervention.

Conclusion: Findings from this study suggest that a significant proportion of PPI prescriptions do not align with current guideline recommendations. This emphasises the need for continuous and multidimensional improvement strategies and interventions on alignment of prescribing practice with guidelines, particularly in high-pressure primary care settings.

Introduction: There is a known discrepancy between symptoms reporting and histological disease activity in patients with eosinophilic esophagitis (EoE) such that patients with EoE in histological remission may still report symptoms while patients with histologically active EoE may report few or no symptoms. Esophageal symptom-specific anxiety, hypervigilance, and adaptive behaviours at mealtime may affect dysphagia reporting in EoE but this has not been investigated.

Aims & Methods: We investigated the role of esophageal symptom-specific anxiety, hypervigilance, and adaptive behaviours at mealtime on dysphagia reporting in patients with EoE.

Consecutive adults (>18 years) with histologically active or inactive EoE (i.e., ≥ 15 or < 15 eosinophils/high-power field) at their last upper endoscopy (EGD) were prospectively enrolled. For each patient, esophageal hypervigilance, anxiety, and adaptive behaviours were assessed prior to the EGD by a physician who was blind to patients' treatment status and histological disease activity. Esophageal anxiety and hypervigilance were assessed using the validated Esophageal Hypervigilance and Anxiety Scale (EHAS) with a 30-day recall, while the validated Dysphagia Symptom Questionnaire (DSQ) and Dysphagia Symptom Score (DSS) were used for quantification of dysphagia. A structured interview (Pisa adaptation questionnaire, PiEAQ) was used for the assessment of adaptive behaviours (including: drinking water to push the bolus, lubricating food, chewing for long, and blending food) over the 30 days prior to the EGD. Kruskal-Wallis Rank Sum Test and Pearson's Chi-squared were used for comparisons as appropriate. ROC curve analysis was used to calculate the diagnostic accuracy (AUC). Significance threshold was $p < 0.05$.

Results: Seventy-one patients were included. Sixty-two percent ($n=44$) had histologically active EoE and 38% ($n=27$) were in histological remission. High anxiety, hypervigilance, and use of adaptive behaviours were found in 49.3%, 46.5%, and 56.3% of patients, respectively. Higher levels of anxiety were associated with an increased severity of dysphagia according to DSQ and DSS scores ($p=0.02$ and $p=0.003$, respectively), whereas this was not true for hypervigilance ($p=0.79$ and $p=0.24$, respectively). Adaptive behaviours were significantly more commonly used by histologically active EoE compared to EoE in remission (72.3% vs 29.6%, $p < 0.001$). The DSQ and DSS scores of patients using any or a combination of adaptive behaviours were comparable to those of patients not using any adaptive behaviour at mealtime ($p > 0.1$ for all comparisons), suggesting a marginal impact of adaptive behaviours on dysphagia reporting. Based on ROC curve analysis, the AUC of the DSQ for the assessment of histological disease activity was 0.72 (DeLong 95% CI, 0.60-0.83), while the AUC of the DSS was 0.69 (DeLong 95% CI, 0.56-0.82). Dysphagia reporting adjustments based on anxiety or hypervigilance sub-scores of the EHAS or on the presence of adaptive behaviours at mealtime did not modify the performance of the DSQ and DSS.

		Patients with high esophageal anxiety (n=35)	Patients with low esophageal anxiety (n=36)	p value
Full population n=71	DSQ	3 [0-5]	2 [0-3]	$p=0.02$
(EHAS subscore cut-off>8)	DSS	5 [0-6]	2 [0-3]	$p=0.003$
		Patients with high esophageal hypervigilance (n=33)	Patients with low esophageal hypervigilance (n=38)	
Full population n=71	DSQ	2 [0-3]	2 [0-3]	$p=0.79$
(EHAS subscore cut-off>11)	DSS	3 [0-6]	2 [0-4]	$p=0.24$

Conclusion: Esophageal anxiety, hypervigilance, and adaptive behaviours can be found in half of EoE patients regardless of histological disease activity. Esophageal anxiety contributes to dysphagia severity in patients with EoE, while hypervigilance does not. The use of adaptive behaviours is associated with histologically active EoE and represents a clinical marker of disease activity but does not affect dysphagia reporting.

Disclosure: Nothing to disclose.

CLINICAL EFFECTIVENESS AND SAFETY OF ESOPHAGEAL STRICTURE DILATION USING A NOVEL ENDOSCOPIC ATTACHMENT CAP (BOUGIECAP VERSION 2.0) IN ADULTS WITH EOSINOPHILIC ESOPHAGITIS

Introduction: The BougieCap (Ovesco Endoscopy AG, Tübingen, Germany) is a cone-shaped transparent plastic cap attached by an adhesive tape to the tip of the endoscope and allows optical and tactile feedback during stricture dilation. In 2021, our group published on a one-time esophageal stricture dilation using the first version of BougieCap in 50 adults with EoE and were able to show its efficacy and safety. However, one BougieCap got detached during endoscopy. Ovesco recently released an upgraded BougieCap (version 2.0) that is characterized by the following features: 1) improved adhesive power of the tape; 2) gradual dilation over two millimeters per cap; 3) improved fit of the connecting part of the cap with the endoscope. As of yet, the technical feasibility, safety and clinical effectiveness of BougieCap version 2.0 for stricture dilation in adult EoE patients is unknown.

Aims & Methods: EoE patients prospectively included in the Swiss EoE Cohort were dilated with BougieCap 2.0 in case of the presence of esophageal strictures and stricture-related symptoms. Symptoms were assessed before and two weeks after a single dilation session using the validated EESAI PRO tool (range 0-100 points). This is an investigator-initiated study. None of the authors has financial ties with Ovesco Endoscopy AG.

Results: Forty two patients (76.2% male, median age 40 years (IQR 31-54 years), median disease duration 5 years (IQR 4-8 years), median diagnostic delay of 4 years (IQR 3-5 years), 57.2% treated with swallowed topical corticosteroids, 19.1% with proton pump inhibitors, 9.5% without anti-eosinophil therapy, 7.1% with elimination diet, 4.8% treated with dupilumab, 2.4% treated with benralizumab) were evaluated. Endoscopic bougienage was technically successful in 100%. A stricture diameter of < 10 mm was found in 14.3% of patients. Strictures were located in 38.1% in the prox-

imal esophagus, in 57.4% in the distal esophagus, and in 4.8% in both proximal and distal esophagus. Median esophageal diameter increased from 12 mm (IQR 12-13) to 14mm (IQR 14-16, $p<0.001$). Median EEsAI PRO dropped from 35 points (IQR 27-42) to 0 (IQR 0-12, $p<0.001$) at 2 weeks post dilation. There was no bleeding necessitating endoscopic intervention. Temporary post-dilational thoracic pain was reported by 33.3% of patients. No esophageal perforation was observed and no BougieCap got detached. One BougieCap was used in 66.7% of dilations whereas two BougieCaps were used in 33.3% of procedures. Median esophageal peak eosinophil count was 10/hpf (IQR 0-24).

Conclusion: In adults with EoE, endoscopic treatment of esophageal strictures using the upgraded BougieCap version 2.0 is technically feasible, safe and offers symptomatic improvement in the short term.

Disclosure: Nothing to disclose.

INTERIM FEASIBILITY OUTCOMES FROM THE FIRST REAL-WORLD PROSPECTIVE CAPSULE SPONGE IN EOSINOPHILIC OESOPHAGITIS STUDY (COSIE)

A.A. Rai¹, F. Coli¹, P. Baker¹, K. Shaw¹, M. O'Donovan², D. Morris¹

¹Lister Hospital; East and North Hertfordshire NHS trust, Gastroenterology, Stevenage, United Kingdom, ²Cyted Laboratory, Cyted Pathology Laboratory, Cambridge, United Kingdom

Contact E-Mail Address: Ayeshaaslamrai@gmail.com

Introduction: Eosinophilic oesophagitis is a condition characterised by symptoms of dysphagia and/or food impaction in adults, with oesophageal histology showing a peak eosinophil count of >15 eosinophils/high power field (or >15 eosinophils/ 0.3mm^2 or >60 eosinophils / mm^2), and the absence of other causes¹. Recent BSG guidelines for the management of Eosinophilic oesophagitis (EOE) in adults recommend repeat endoscopy to ensure histological remission on treatment. This can require multiple procedures that are unpleasant for patients and are resource intensive. Capsule sponge is a minimally invasive oesophageal cell sampling technology that has been used in >15000 patients with Reflux symptoms and Barrett's oesophagus. To date it has not been used in adults with EOE in clinical practice. The COSIE study is a pragmatic prospective ongoing study of adults with non-stenotic EOE to evaluate capsule sponge in routine clinical practice.

Aims & Methods: All adult patients attending a monthly dedicated EOE clinic May 2023 to April 2024 in a non-specialist hospital, were screened by a single consultant. Patients were offered capsule sponge and same day gastroscopy at least 8 weeks after starting or changing therapy or after three weeks from first diagnostic gastroscopy to monitor disease response and activity. The Endosign device was used in all patients. The Dysphagia Symptom Questionnaire, cytological and histological eosinophil count and Endoscopic reference score (EREFS) were measured as part of the ongoing study. Qualitative outcomes including success rate of swallowing, satisfactory cell sample (sufficient squamous cells), evidence of sponge reaching the stomach (columnar cells seen), complications and patient feedback and test preference were collected patient satisfaction questionnaire was collected after the procedure on the same day. All sponge cytology were processed by CYTED laboratories and endoscopic histology as part of normal clinical practice.

Results: 138 patients with EOE attended the clinic between May 2023 and April 2024. 77 patients identified as suitable, 41/53 (75%) agreed to take part. 12/53 (25%) declined to take part in the study when our research nurse contacted them and 24 are awaiting testing. 31/41 (75.6%) were male and 10 (24.4%) females. Median age observed was 50 years, standard deviation 14.58, minimum was 19 years old and maximum age

recorded was 72 years. Of the 41 patients who attempted to swallow capsule sponge 5 (12%) failed to swallow after 2 attempts. There have been no complications and no sponge detachments. 36 /41 (87.8%) agreed to same day gastroscopy. On same day gastroscopy examination, 20/36(55.5%) had minor grade I or II visible abrasions. No mucosal tears were evident. There was evidence of the capsule sponge reaching the stomach in 29/32 (90.6%). Adequate squamous cytological specimen were produced in 32/32 (100%). 36 (87.8%) patients found test acceptable of which 28/37 (75.6%) of those who expressed a preference preferred capsule sponge to gastroscopy.

Conclusion: The preliminary results show that capsule sponge is feasible to use in routine clinical practice and can be used safely to sample the oesophagus in non-stenotic EOE, providing sufficient samples. It is well tolerated and patients preferred capsule sponge to gastroscopy. Ongoing work will assess clinical effectiveness and management outcomes, comparative eosinophil counts and will contribute to a multicentre QU-BIE (QUantitative Biomarker Identification for Eosinophilic oesophagitis) study to evaluate potential biomarkers in EOE.

NETWORK META-ANALYSIS COMPARING EFFICACY OF CONVENTIONAL THERAPY AND BIOLOGICS TO PREVENT ENDOSCOPIC POSTOPERATIVE RECURRENCE IN PATIENTS WITH CROHN'S DISEASE

M. Hupé¹, N. Mathieu¹, B. Pereira², A. Buisson²

¹CHU de Grenoble, IBD Unit, Grenoble, France, ²CHU Estaing Clermont-Ferrand, IBD Unit, Clermont-ferrand, France

Contact E-Mail Address: mariannehupe@hotmail.fr

Introduction: As no direct comparison between IBD drugs to prevent endoscopic postoperative recurrence (POR) in Crohn's disease (CD) are available, hierarchizing these therapeutic options remains challenging.

Aims & Methods: The objective of this network meta-analysis was to compare the effectiveness of treatments to prevent endoscopic POR of CD. We performed a systematic review and network meta-analysis of comparative studies conducted in adults, evaluating a treatment to prevent endoscopic POR after ileocecal resection. The selection of studies was made according to PRISMA guidelines. The primary endpoint was endoscopic POR at 6 months defined as Rutgeerts score $\geq$ i2.

The network meta-analysis was carried out according to a random effects model. The results are presented as odds ratio (OR) with 95% confidence interval, adjusted for risk factors of POR. The risk of bias of the studies was assessed according to the Cochrane risk-of-bias tool for randomized trials and overall statistical heterogeneity between studies was assessed using τ . The SUCRA ranking method (surface under the cumulative ranking) was used to rank the treatments.

Results: Twenty studies were included in this network meta-analysis, including a total of 2414 patients. Overall heterogeneity was moderate ($\tau = 0.34$). After adjustment for POR risk factors, ustekinumab (OR = 0.23 [0.07-0.70]), vedolizumab (OR = 0.17 [0.05-0.59]), infliximab (OR = 0.18 [0.36-0.88]) and adalimumab (OR = 0.17 [0.07-0.42]) were superior to placebo to prevent endoscopic POR, contrary to 5-ASA (OR = 0.79 [0.42-1.48]) and thiopurines (RR = 0.52 [0.22-1.24]) (Table 1). Ustekinumab (OR = 0.29 [0.08-0.99]), vedolizumab (OR = 0.22 [0.06-0.85]), infliximab (OR = 0.23 [0.09-0.54]) and adalimumab (OR = 0.22 [0.08-0.59]) were more effective than 5-ASA in preventing endoscopic POR. Adalimumab (OR = 0.33 [0.15-0.74]) and infliximab (OR = 0.34 [0.13-0.87]) were also more effective than thiopurines.

We observed no difference in efficacy between the 4 biologics (infliximab, adalimumab, ustekinumab and vedolizumab). The SUCRA ranking identified adalimumab (SUCRA = 0.81), infliximab (SUCRA = 0.80), vedolizumab (SUCRA = 0.79) and ustekinumab (SUCRA = 0.72) as the most effective treatments. The probability that thiopurines (SUCRA = 0.41), 5-ASA (SUCRA = 0.24), placebo (SUCRA = 0.16) and antibiotics (SUCRA = 0.08) were significantly higher weak.

Conclusion: This network meta-analysis confirms the efficacy of anti-TNF agents, vedolizumab and ustekinumab in preventing endoscopic CD POR without any difference between them. When prophylactic therapy is indicated, biologics appear as the best therapeutic option to prevent of endoscopic POR. Due to lower effectiveness, the use of 5-ASA and thiopurines should be limited in this situation.

Introduction: Ileocecal resection (ICR) is the most common surgical procedure for ileal Crohn's disease (CD). Data is growing to suggest ICR in localized disease as a first-line treatment instead of biologics to maintain long-term remission. However, removal of the ileocecal valve has a detrimental effect on bowel transit and disabling symptoms may occur after surgery. We aimed to assess the impact of a primary ICR on the daily symptoms of patients with CD.

Aims & Methods: All patients who underwent a primary ileocecal resection at the Saint-Antoine Hospital between January 2017 and December 2022 were included. Patients were followed up with post-operative visits before and after Rutgeerts score assessment. Patients' daily symptoms were recorded using a dedicated database (SUVIMIC), the routine software used at the Saint-Antoine Hospital that includes assessment of patient reported outcomes.

Results: Between 2017 and 2022, 110 patients underwent primary ICR for CD in relapse at the Saint-Antoine Hospital. The median disease duration at surgery was 6 years (IQR 1–11). The indications for surgery were fistulizing CD phenotype for 62 patients (56.4%) and strictures for 40 patients (36.4%). Only 7 patients (6.4%) had inflammatory phenotype at the time of first ICR. The median time to Rutgeerts Score assessment was 7 months showing 75 patients (68.2%) in remission defined as a score of i0, i1, i2a and 35 patients (31.8%) in relapse with a score of i2b to i4. Patients' daily symptoms reported at endoscopic assessment (6 – 12 months after surgery) are shown in Table 1.

Patients' daily symptoms	According to disease activity		According to small bowel removed		
	Remission n = 75	Relapse n = 35	Short resection $\leq$ 20 cm n = 47	Resection 21 – 40 cm n = 46	Long resection $\geq$ 41 cm n = 17
Liquid stools	44 (58.7)	19 (54.3)	29 (61.7)	21 (45.7)	13 (76.5)
> 3 liquid stools per day	7 (9.3)	6 (17.1)	7 (14.9)	2 (4.3)	4 (23.5)
Number of liquid stools per day mean (SD)	1.4 (1.5)	1.9 (1.5)	1.8 (2.4)	1.1 (1.5)	2.1 (1.7)
Fecal urgency	17 (22.7)	9 (25.7)	12 (25.5)	6 (13.0)	8 (47.1)
Fecal incontinence	1 (1.3)	3 (8.6)	1 (2.1)	1 (2.2)	2 (11.8)
Anti-diarrheal medications	17 (22.7)	7 (20.0)	9 (19.2)	11 (23.9)	4 (23.5)
Abdominal pain	21 (28.0)	14 (40.0)	15 (31.9)	12 (26.1)	8 (47.1)
Fatigue	24 (32.0)	14 (40.0)	15 (31.9)	16 (34.8)	7 (41.2)

Table 1. Daily symptoms of patients after primary ileocecal resection at endoscopic assessment

Symptoms are expressed in number of patients (%). Remission was defined as a Rutgeerts score i0, i1, i2a and relapse i2b, i3 and i4.

According to disease activity, the prevalence of diarrhea, defined as liquid stools, was 58.7% in patients in remission and 54.3% in patients in relapse. The prevalence of fecal urgency was 22.7% and 25.7%, respectively. Fecal incontinence was present in one patient in remission and three patients in relapse. According to the length of the resected small bowel, liquid stools

were observed in 61.7% of patients with short resections (≤ 20 cm), 45.7% of patients with resections between 21 - 40 cm and 76.5% of patients with long resections (≥ 41 cm). Fecal urgency was present in 25.5%, 13.0% and 47.1% respectively. Furthermore, the prevalence of abdominal pain was 31.8% and of fatigue 34.5% in the whole cohort.

Conclusion: The prevalence of digestive symptoms after primary ICR for CD is high, especially diarrhea and fecal urgency, even in patients in remission. Primary ICR for CD is an effective treatment for achieving long-term remission, but removal of the ileocecal valve leads to irreversible changes in bowel transit, which must be considered before proposing surgery.

Introduction: Postoperative recurrence (POR) in patients with Crohn's disease (CD) occurs mostly within the first year after ileocolic resection. POR can be prevented efficiently with early postoperative use of thiopurines or anti-TNF agents. Recently, it has been reported that medical prevention for POR might also reduce the risk of delayed POR.

Aims & Methods: Aims: To assess the long-term risk of a second intestinal resection for CD according to the use of early medical prevention of POR. Methods: Adult patients with CD who underwent a first ileocolic resection with ileocolic anastomosis between 1990 and 2020 and at least one year of clinical follow-up were identified from the Spanish ENEIDA registry. Patients in whom ileocolic resection was due to cancer were excluded. Medical prevention of POR was defined as any immunomodulator or biological agent started within the first 6 months after the ileocolic resection and maintained for at least 3 months. Medical treatment of POR was defined as any immunomodulator or biological agent started at least 6 months after the index surgery. Surgical POR was defined as the need for a second intestinal resection at least 6 months after the first ileocolic resection.

Results: A total of 5,084 patients were included. Main characteristics of the whole cohort were as follows: 51% men, 39% active smokers at the first surgery, 40% penetrating and 40% stricturing behaviour, 25% perianal disease. 34% exposed to immunomodulators and 25% to biologicals before the first surgery. Median disease duration at first surgery of 3 years (range, 0-46), median age at index surgery was 35 years (range, 9-89), median follow-up until second resection or last visit of 125 months (range 6-408). 55% followed medical prophylaxis (33% thiopurines, 10% biological monotherapy, 12% combotherapy). Surgical POR occurred in 17% of the whole cohort. Kaplan-Meier survival curves showed a significantly higher risk of surgical POR among patients who did not follow medical prevention ($P<0.0001$), whether with thiopurines ($P<0.0001$) or biologicals ($P<0.0001$). No differences in surgical POR were observed between medical prevention with biologicals in monotherapy or combotherapy ($P=0.588$) nor between thiopurines and biologicals ($P=0.114$). In the Cox regression analysis, medical prevention with thiopurines (HR 0.65, 95%CI 0.56-0.76; $P<0.0001$) and medical treatment with biologicals (HR 0.87, 95%CI 0.80-0.94; $P<0.0001$) or thiopurines (HR 0.88, 95%CI 0.78-0.99; $P<0.032$) were independent protective factors of surgical POR.

Conclusion: Early medical prevention (particularly with thiopurines) seems to have a long-term beneficial effect on preventing surgical POR. Our findings support the systematic use of early medical prevention instead of endoscopy-driven strategies in the postoperative setting of CD.

IMPACT OF TIMING OF PROPHYLAXIS THERAPY ON POST-OPERATIVE ENDOSCOPIC RECURRENCE IN A REAL-LIFE COHORT OF PATIENTS WITH CROHN'S DISEASE

Introduction: Despite significant advancements in medical therapy, surgery remains a common option for managing Crohn's disease (CD), especially in cases of complicated disease, with a 10-year risk of surgical resection (SR) of approximately 50%. (1)

Furthermore, it is well-established that the majority of patients experience subsequent relapse after surgery, with up to 90% develop endoscopic post-operative recurrence (POR) within one year. (2)

Several guidelines for managing post-operative CD recommend using pre-operative risk factor stratification to determine the use of prophylactic biologic therapy against POR in high-risk individuals. However, the optimal timing for initiating biologic therapy after resection surgery has not been established, and the impact of a delayed start remains unclear, particularly outside the context of clinical trials. A recent study demonstrated that initiating an anti-TNF agent within 4 weeks after SR was associated with a reduction in POR. (3)

However, the comparison was made against patients receiving no prophylaxis with biologic drugs.

Aims & Methods: Our study aims to assess the impact of the timing of biologic therapy initiation on endoscopic recurrence after resection surgery in CD. We conducted a single-center, retrospective study evaluating endoscopic outcomes of CD patients who underwent ileo-colonic resection. All patients underwent their first endoscopic evaluation within 6-12 months after surgery to assess POR, using the Rutgeerts score (RS), with POR defined as RS $\geq$ 2. All patients received biological therapy for recurrence prevention within 16 weeks after surgery.

Results: We included 177 patients, with a median age at surgery of 38 years old. The primary indication for surgery was stenotic disease. 77% of patients had no prior history of bowel resection and 38% were bio-naïve. All patients had at least one risk factor for post-surgical recurrence, including smoking or penetrating disease. Prophylactic biologic therapy (22% Infliximab, 53% Adalimumab, 8% Vedolizumab, and 17% Ustekinumab) was administered to all patients, with initiation within 4 weeks, 4-8 weeks, 8-12 weeks, and 12-16 weeks in 20%, 32%, 15%, and 33% of patients, respectively. POR was observed in 50% of the entire cohort at 6-12 months.

Starting therapy within 12 weeks following SR was associated with a significantly lower recurrence rate than initiating therapy beyond 12 weeks (POR: 36% vs 64% $p < 0.01$).

Notably, induction within 8 weeks showed a lower recurrence rate than after 8 weeks (POR: 39% vs 61%; $p < 0.05$). There was no significant difference in recurrence rate between starting therapy within 4 weeks and 8 weeks, even when stratifying by risk factors for recurrence. Furthermore, for patients already on biologic therapy prior to SR, therapy was either

maintained unchanged, switched, or swapped in 54%, 18%, and 28% of patients, respectively. Investigating the impact of these strategies on POR, we noted significant differences, with less recurrence for those who continued the same therapy after SR (POR: 42% vs 61% vs 72%; $p < 0.05$). However, the mean time to therapy resumption in this group was also significantly shorter than in the others (weeks 9.7 vs 15 vs 13; $p < 0.05$).

Conclusion: In our a real-life cohort, we found that prophylaxis administered within 12 weeks after resection correlates more strongly with a reduced risk of post-operative recurrence. Furthermore, in this group, our results indicate a lower risk of recurrence in patients receiving prophylaxis within 8 weeks. However, larger clinical studies are needed to confirm these results.

Introduction: The evidence guiding management of patients with inflammatory bowel disease (IBD) and permanent ileostomy (PI) is limited. We aimed to summarize the evidence for interventional studies related to adjunctive ostomy care including management of high stoma output,

skin care, stoma appliances, adhesives, behavioural interventions, mental health, diet, nutrition and disease recurrence.

Aims & Methods: MEDLINE, Embase, and Cochrane CENTRAL were searched from inception to January 5, 2024. Eligible studies were randomized controlled trials (RCTs), non-randomized controlled studies, or comparative cohort studies in English. Studies predominantly recruiting participants with ulcerative colitis (UC) and/or Crohn's disease (CD) with PI were considered. Studies assessing temporary ileostomy, and ostomies other than PI such as colostomy, urostomy, and jejunostomy were excluded.

Authors, Year	Country	Study design	Number of participants	IBD subclass (n)	Intervention	Control	Outcomes	Conclusions
Tytgat, 1976	Netherlands	Double-blinded, RCT, cross over	20, ileostomy (total colonic resections with PI)	UC (12) CD (5) Polyposis coli (2) Adenocarcinoma (1)	Loperamide 8mg/day (first four days) and were allowed to increase the dose to 12mg/day for the next 3 days)	Placebo	Ileostomy fecal output	Daily fecal outputs were significantly lower with loperamide compared to placebo
Berghouse, 1984	United Kingdom	Unblinded, randomized, ileostomies cross over,	10 patients with	CD (5) UC (5)	Diet rich in refined carbohydrates	Diet with unrefined carbohydrates	Microbial composition of ileostomy output	Approximately 10-fold increase of total bacteria per gram of effluent when patients were on diet with unrefined carbohydrates. Significantly low wet and dry weight of ileostomy output with diet rich in refined carbohydrates
Sandberg-Gertzen, 1986	Denmark	Double-blinded RCT, placebo-controlled cross over	8 patients who underwent colectomy with a PI	UC	Azodisal sodium (1 g/day vs 2 g/day) or sulphasalazine (2 g/day) given for five day periods	placebo	Ileostomy fluid output. Prostaglandin levels in ileostomy output	Azodisal sodium but not sulfasalazine was associated with increased ileostomy output and was dose related. Azodisal sodium was not associated with increased prostaglandin levels in ileostomy output.
Jarnerot, 1988	Sweden	Double-blinded, placebo-controlled RCT cross over	8 patients who underwent colectomy with a PI	UC	Olsalazine sodium 0.75g twice a day	Placebo	Bile acids in ileostomy output	Bile acid excretion was not significant different between Olsalazine and placebo
Ecker, 2003	Germany	Double-blinded RCT	40 patients with ileostomy and with a high ileostomy output (>1000 ml/24)	CD	Oral budesonide 3mg tid x 8 days	Placebo	A >25% reduction in intestinal output during treatment was defined as response	60% (12/20) of patients showed a response compared to none in placebo group. 30.2% decrease in median output was seen in budesonide group compared to 0.3% decrease in placebo group
Rud, 2019	Denmark	Double-blinded, active ileostomy and comparator-independent controlled RCT cross over	8 patients with ileostomy and parenteral nutrition	UC (5) CD (2) Cancer (1)	Iso-osmolar (279 mOsm/kg) oral supplement 200ml x 4 times a day for two days	Hyper-osmolar (681 mOsm/kg) oral supplement 200ml x 4 times a day for two days	Difference in ileostomy output	No statistically significant changes in ileostomy output. Iso-osmolar supplement induced a statistically significant increase in urine volume and natriuresis

Table 1. Characteristics of interventional studies conducted in patients of inflammatory bowel disease and permanent ileostomy

CD: Crohn's disease, PI: permanent ileostomy, RCT: randomized controlled trial, UC: ulcerative colitis.

Results: A total of 3217 records were identified and independently screened of which six studies were eligible (Table 1). Five studies were published more than 20 years ago (1976-2003) with a small sample size (ranged from 8 to 40). Five studies were double blind RCTs with four studies incorporating a cross over design, and one was non-blinded RCT with a cross over design. Two studies exclusively included patients with UC, one study included CD and the remaining three studies included both UC and CD. No studies included patients with active CD. Four studies assessed pharmacological interventions (loperamide, 5-aminosalicylate [5-ASA], azodisal sodium, and oral budesonide), one assessed oral supplement with different osmolarities and one assessed dietary interven-

tion (unrefined vs. refined carbohydrate). Decrease in ileostomy output was primary outcome of interest in four studies (Loperamide, budesonide and azodisal sodium). Outcomes of the remaining two studies include changes in microbial composition and bile acid excretion. Loperamide and budesonide were associated with decreased stoma output. In a study assessing dietary intervention, patients receiving diet rich in unrefined carbohydrates had a ten-fold increase in bacterial load in stoma output compared to patients on a diet rich in refined carbohydrates. One study reported no difference in stoma output between iso- and hyper-osmolar supplements but iso-osmolar supplements were associated with increased natriuresis. The remaining studies were designed to explore the effect of 5-ASAs on ileostomy output in patients with UC and PI.

Conclusion: This study highlights that the evidence base to inform care for patients with IBD and PI is almost non-existent. There is an urgent need for focused research in this area to inform evidence-based treatment decisions. The items identified in this review as well as knowledge gaps will inform consensus steps for development of future care pathways and expert guidelines.

PERIOPERATIVE HYPERGLYCEMIA AND RISK OF SURGICAL COMPLICATIONS IN CROHN'S PATIENTS

Introduction: Perioperative hyperglycemia, in diabetic and non diabetic patients undergoing surgery, is known to be associated with increased rates of surgical site infection (SSI), myocardial infarction, stroke and other postoperative adverse events^{1,2}. No data are available in literature regarding the potential relationship between hyperglycemia and postoperative complications in Crohn's patients. Aim of the paper is to study the association between perioperative hyperglycemia and adverse events in a surgical cohort from two IBD Tertiary Care hospitals.

Aims & Methods: This study is a retrospective analysis of a prospectively maintained database. All patients undergoing first surgery for ileo-colonic Crohn between 2012 and 2023 were included. Patient cohort was divided in three subgroups according to the preoperative serum level of glycemia: <100 mg/dL, 100-126 mg/dL and > 126mg/dL. All postoperative complications were collected and categorized according the Clavien-Dindo classification³.

Results: In the study period, 641 patients were included, 389 (60.7%) males and 252 (39.3%) females. 7 (1.1%) were known diabetic patients. The mean preoperative serum level of glycemia was 97.23 ± 22.1 mg/dL and the mean postoperative level was 107.92 ± 29.7 mg/dL. Preoperative glycemia > 100 g/dL was related to a significant more frequent rate of complications (p<0.01; OR 3.34). Also elderly age (> 65 years old) and preoperative serum albumin < 35 g/L were found significant risk factors for postoperative complications: respectively with p< 0.01 (OR 1.01) and p< 0.04 (OR 1.97). The percentage of complications was gradually increased with the augmentation of the preoperative hyperglycemia with a statistically significant difference: 22.6% in the group with <100 mg/dL, 47.9% in the 100-126 mg/dL group and 56.2% in >126 mg/dL group (p< 0.01). Wound infection, abdominal abscess and postoperative ileus were statistically more frequent in Crohn's patients with preoperative glycemia> 100 gm/dL, respectively with p<0.001, p< 0.01 and p< 0.013.

Conclusion: Our study confirms that the risk of post-operative adverse events for Crohn's patients, as previously highlighted for general surgical population, appears to be linked to preoperative hyperglycemia. A prompt control of glycemia levels in the perioperative period could help to reduce significantly the rate of surgical complications in this already challenging and demanding disease.

TEMPORAL TRENDS IN COLECTOMY AND MORTALITY RATES FOLLOWING SURGERY FOR ULCERATIVE COLITIS IN ENGLAND: 2005-2020

J. Couch¹, K. Thomas¹, T. Card¹, D. Humes¹

¹University of Nottingham, Nottingham, United Kingdom

Contact E-Mail Address: david.humes@nottingham.ac.uk

Introduction: The incidence of Ulcerative Colitis (UC) in the England has changed little over the last fifteen years (1,2). Medical and surgical management however has transformed during that period. Our aim was to investigate whether colectomy rates and 90-day mortality following surgery have changed in the last two decades.

Aims & Methods: This was a population-based cohort study using computerized health records from Clinical Practice Research Datalink linked to Hospital Episode Statistics and Office of National Statistics data. An incident cohort was defined as patients with a new diagnosis of UC between 2005-2020.

Time to first colectomy was calculated from diagnosis date. Cumulative incidence of colectomy and 90-day mortality was calculated using life tables. Colectomy rates following UC diagnosis were calculated annually for each year between 2005 and 2020 using the denominator of total person time contributing to that year. Rates were modelled using Poisson regression analysis. Cox regression was used to model the risk of surgery and 90-day mortality rates and the effect of gender, socioeconomic status and region. Analysis was performed using StataMP 18.

Results: 46,730 patients had an incident diagnosis of UC, 49.33% (23,055/46730) were female. 5.72% (2672/46730) underwent colectomy. The one year risk of colectomy was 2.32% (95% CI 2.19-2.47%), with a 5-year risk of 4.92% (95% CI 4.72-5.13%) and 10-year risk of 6.47% (95% CI 6.22-6.73%). 90-day mortality for emergency and elective colectomy was 3.54% (95% CI 2.73-4.58%) and 1.44% (95% CI 0.92-2.25%) respectively. Total colectomy rate fell from 17.15 per 1000 person-years in 2005 to 5.96 per 1000 person years in 2020 (IRR 0.35, 95% CI 0.27-0.45). Elective colectomy rates fell from 6.78 per 1000 person-years in 2005 to 2.75 per 1000 person-years in 2020, (IRR 0.41, 95% CI 0.27-0.60). Emergency colectomy rates fell from 10.37 per 1000 person-years in 2005 to 3.21 per 1000 person-years in 2020 (IRR 0.31, 95% CI 0.22-0.43).

Females were 30% less likely to undergo colectomy (HR 0.70, 95% CI 0.65-0.75). There was a statistically significant difference in risk of colectomy by region with London, South East, East of England and North West having lower colectomy rates than West Midlands and the North East. There was no significant difference between gender, region or socioeconomic status for 90-day mortality.

Conclusion: There has been a significant reduction in both elective and emergency colectomy rates between 2005-2020. There was gender and regional variation in risk of colectomy. Further work may attempt to correlate these findings with prescription rates of particular medications to elicit a cause for these findings.

Introduction: Chronic complications are common among patients with ulcerative colitis (UC) undergoing Ileal Pouch-Anal Anastomosis (IPAA)^{1,2}. To predict who may benefit most from IPAA, we focused on patients maintaining a normal pouch phenotype for over a decade, seeking which biomarkers identify this unique group.

Aims & Methods: All patients with UC after IPAA who were followed at the Rabin Medical Center comprehensive pouch clinic and consented to prospective observational follow-up were included. Patients with familial adenomatous polyposis or ileostomy were excluded.

“Ultra-normal” pouch phenotype was defined as both clinically and endoscopically normal pouch phenotype, with no episodes of acute pouchitis over 10 years post-ileostomy closure. We assessed demographic data; disease course; peri-operative factors; and inflammatory, serology, and genetic markers. We compared “ultra-normal” patients to “rapid complicators”, defined by the development of chronic pouchitis or Crohn’s-like disease of the pouch within five years post-ileostomy closure.

Results: Of over 400 patients, 174 consented to prospective follow-up; of these, 18 were excluded due to FAP and 8 due to ileostomy. Of the 148 qualifying for final analysis, 26 (17.5%) maintained an “ultra-normal” phenotype over an average of 20±7.14 years since ileostomy closure, while 32 (21%) were classified as “rapid complicators”.

The “ultra-normal” group (mean age, 55.2±13.3 years; females: 50%) had an average age at UC diagnosis of 23.7±10.0 years and age at surgery of 34.9±12.3 years. In comparison, the “rapid complicators” group had an average age at diagnosis of 22.3±15.1 years (p=0.25) and age at surgery of 31.1±16.9 years (p=0.2).

Repeated measurements during our study follow-up period found that “ultra-normal” patients maintained an average BMI of 27.2±6.2 kg/m² and hemoglobin, C-reactive protein, and fecal calprotectin levels of 14.0±1.45 g/dL, 0.63±0.56 mg/dL, and 190.8±169.0 µg/g, respectively. Their average Short Inflammatory Bowel Disease Questionnaire (SIBDQ) score was 55.6±10.2; average Pouchitis Disease Activity Index (PDAI) score was 2.7±1.7. None required post-operative steroidal, immunomodulator, or biologic treatment. Probiotics were intermittently used by 12 patients (46%).

Non-Ashkenazi Jewish origin was more common in the “ultra-normal” group (62% vs. 34%) than Ashkenazi Jewish (38% vs. 41%) and Arabs (0% vs. 22%), p=0.016. No patient in the “ultra-normal” group had NOD2 polymorphism, compared to 3 heterozygotes among “rapid complicators” (p=0.23). Pre-operative disease extent was similar between groups (p=0.64), as was the indication for IPAA, with 77% of “ultra-normal” patients and 78% of “rapid complicators” having refractory or severe disease as the surgery indication (p>0.99). However, pre-operative biologic therapy, mostly with anti-tumor necrosis factor agents, was independently significantly more

common among “rapid complicators” (75% vs. 19% in “ultra-normal”, p<0.001).

Conclusion: “Ultra-normal”, uncomplicated pouch phenotype for two decades after IPAA is sustained in a minority (~ fifth) of patients. While similar to “rapid complicators” in pre-operative disease course and indication for surgery, patients with “ultra-normal” pouch received less pre-IPAA biologic therapy. These findings may contribute to post-IPAA prognostication and, if validated, may affect pre-operative treatment decisions.

COMPARATIVE ANALYSIS OF SHORT- AND LONG-TERM RESULTS BETWEEN REDO AND PRIMARY ILEAL-POUCH ANAL ANASTOMOSIS PROCEDURES: A CRITICAL EXAMINATION

T. Braquet¹, M. Collard¹, A. Challine¹, C. Debove¹, N. Chafai¹, Y. Parc¹, J. Lefevre¹

Contact E-Mail Address: lefevre.jeremie@gmail.com

Introduction: Redoing an ileal pouch-anal anastomosis (IPAA) is a rare scenario but the only solution to effectively manage chronic surgical failures. The aim was to compare short- and long-term outcomes after redo-IPAA.

Aims & Methods: All patients who underwent IPAA surgery (primary or redo-IPAA) between 2010 and 2023 were included in this single-center study. Morbidity and ileal-pouch survival were collected. Patients were also administered questionnaires assessing bowel function with the Ileal Pouch Severity Score (IPSS) and the quality of life with the SF36.

Results: 380 primary-IPAA were performed during the inclusion period. Among them, 4% (n=17) required a redo-IPAA. 15 patients were referred to our centre for redo-IPAA. Therefore, 32 patients with redo-IPAA were included. Indication for redo-IPAA were chronic leakage from the previous IPAA (n=15), endoscopically unresectable ileal pouch polyps in FAP patients (n=9), IPAA stenosis (n=4), poor functional results (n=2), twist of the ileal pouch (n=1), invasive adenocarcinoma of the ileal pouch (n=1). Patients had been operated initially for Ulcerative Colitis (n=11), Familial polyposis (n=18) or other causes (n=3).

Median time interval from primary to redo-IPAA was 1.1 years with a minimum of 0.3 year and a maximum of 36 years. The anastomosis was handsewn in 97% of redo-IPAA versus 79% of primary-IPAA (p=0.018).

Manoeuvres to increase mesenteric length were never required during redo-IPAA, whereas it was in 27% of primary-IPAA ($p<0.001$). A diverting stoma to protect the IPAA was performed in 44% of primary-IPAA and in 69% of redo-IPAA ($p=0.007$). Overall postoperative morbidity was lower after redo-IPAA (25%) compared to primary-IPAA (47%, $p=0.016$), as well as hospital stay duration (median 7 days versus 9 days, $p=0.003$). Severe morbidity (redo-IPAA: 16%, primary-IPAA: 21%, $p=0.458$) and anastomotic leakage rate (redo-IPAA: 6%, primary-IPAA: 14%, $p=0.286$) did not differ. Post-operative mortality was nil after redo-IPAA and was 0.3% (1 patient) after primary-IPAA. No patient developed short bowel syndrome.

After a median follow-up of 48 months, ileal-pouch survival was similar between redo-IPAA and primary-IPAA groups (5-year ileal-pouch survival: 82% versus 90% respectively, log-rank test: $p=0.250$). Long-term rate of anastomotic stenosis was similar after redo-IPAA (18%) compared to primary-IPAA (12%, $p=0.365$). Among patients with a technical success of the IPAA procedure, the rate of definitive stoma due to a poor bowel functional result was 14% after redo-IPAA versus 8% after primary-IPAA ($p=0.401$). Long-term bowel function was significantly worse after redo-IPAA (median IPSS score: 56/100) compared to primary-IPAA (median IPSS score: 41/100, $p=0.007$), without impacting quality of life measured by the SF36 score (physical component summary: redo-IPAA: 49/100, primary-IPAA: 50/100, $p=0.501$ and mental component summary: redo-IPAA: 41/100, primary-IPAA: 45/100, $p=0.078$).

Conclusion: Redo-IPAA is feasible with acceptable post-operative morbidity as it showed a similar rates of severe complications, anastomotic leakage, and ileal-pouch survival compared to primary-IPAA. Functional outcomes is worse compared to primary-IPAA but avoid a definitive ileostomy. After a technical success of redo-IPAA, 14% of patients asked for a definitive stoma due to a poor bowel function, thus 86% of patients preferred to maintain digestive continuity with the achieved functional outcome rather than opting for a permanent ileostomy.

FUNCTIONAL POUCH EVALUATION WITH DYNAMIC TRANSPERINEAL ULTRASOUND AND ANO-POUCH MANOMETRY IN ULCERATIVE COLITIS PATIENTS WITH RESTORATIVE PROCTOCOLECTOMY: PRELIMINARY RESULTS

M.L. Vaiano¹, F. Colombo², A. Dell'Era¹, G. Maconi¹, L. Cariola², S. Ardizzone¹, P.G. Danelli²

¹Ospedale Luigi Sacco, Department of Gastroenterology, Milano, Italy, ²Ospedale Luigi Sacco, Department of Surgery, Milano, Italy

Contact E-Mail Address: marialuigia.vaiano@hotmail.com

Introduction: Restorative proctocolectomy is the intervention of choice in patients with refractory or complicated Ulcerative Colitis (UC). Despite the high success rate of the procedure, a minority of patients experiences recurrent symptoms related to pouch dysfunction. To date, neither a gold standard for instrumental diagnosis of such disorders nor specific reference parameters for studying this population have been established.

Aims & Methods: The main aim of this study was to evaluate the role of dynamic transperineal ultrasound (DTPUS) and ano-pouch manometry (APM) in describing functional changes of the pouch and their correlation with clinical symptoms.

This is a prospective observational study conducted on a consecutive unselected sample of patients who underwent restorative proctocolectomy with J pouch for refractory and/or complicated UC in an Inflammatory Bowel Disease (IBD) Tertiary Care Centre. Included patients underwent ileostomy closure at least one year before enrollment. Patients were administered a questionnaire to assess the degree of pouch dysfunction,

followed by DTPUS and APM performed by different operators who were blind to clinical data. Retrospective data regarding surgery and postoperative course were also collected. Fisher's exact test or chi-square test were used for statistical evaluation of the correlation between variables.

Results: 18 patients were analyzed. Based on symptoms severity, they were divided into five groups according to the recently proposed Ileoanal Pouch Syndrome Severity (IPS) score: absence of pouch dysfunction (4), mild dysfunction (4), moderate dysfunction (3), severe dysfunction (2), and extremely severe dysfunction (5). Among DTPUS variables, resting length of puborectalis muscle showed a significant inverse correlation ($p=0.03$) with the degree of pouch dysfunction. More relevant perineal descent and shorter length of puborectalis muscle during strain were also observed in patients with significantly severe dysfunction, although these correlations were not statistically significant ($p=0.08$ and 0.13 respectively). High prevalence of dyssynergic defecation (61%) was also found in all groups, regardless of symptom severity. Among manometric variables, resting basal pressure of the anal sphincter showed an inverse correlation with the severity of pouch dysfunction, albeit without reaching statistical significance ($p=0.12$). Other characteristics observed in all groups, regardless of symptom severity, were a high prevalence of dyssynergic defecation (53%) and absence of the recto-anal inhibitory reflex (77%). Among surgical characteristics, the presence of complications after the first colectomy stage showed significant correlation ($p<0.02$) with subsequent development of clinically relevant pouch dysfunction.

	US FEATURES					P
	0 NO IPS	1 mild IPS	2 moderate IPS	3 severe IPS	4 extremely severe IPS	
Resting length of puborectalis muscle (expressed in mm)	60,4 ± 9,3	64,1 ± 6,7	69,1 ± 1,1	51,8 ± 0,1	53,7 ± 6,3	0,03
Perineal descent (expressed in mm)	9,7 ± 2,6	8,5 ± 6,8	3,3 ± 5,8	14,5 ± 5,7	13,1 ± 2,6	0,08

	MANOMETRIC FEATURES					P
	0 NO IPS	1 mild IPS	2 moderate IPS	3 severe IPS	4 extremely severe IPS	
Resting basal pressure of anal sphincter (expressed in mmHg)	82,2 ± 12,5	86 ± 15,3	74,5 ± 11,2	55,1 ± 26,3	70,6 ± 14,6	0,12

Conclusion: Our preliminary results seems to highlight the role of APM and DTPUS in the diagnosis of functional pouch disorders after restorative proctocolectomy in UC.

Introduction: Endoscopic submucosal dissection (ESD) is an advanced technique that can provide a successful 'en-bloc' and R0 resection rate for large gastrointestinal (GI) lesions. To date, several ESD techniques have been proposed, but their comparative efficacy is still unclear.

Aims & Methods: This network meta-analysis aims to investigate and compare the efficacy and safety of different ESD techniques for resection of colonic lesions. MEDLINE, Embase, Scopus, and the Cochrane Library were systematically searched for randomized controlled trials (RCTs) comparing different ESD techniques through March 2024. The primary outcomes were 'en-bloc' and R0 resection rates. The secondary outcome was the incidence of procedure-related AEs. Direct and indirect comparisons were performed among different ESD techniques. Results were expressed as risk ratio (RR) and 95% confidence interval (CI), using the DerSimonian and Laird random-effects model. The relative ranking of the interventions for achieving the aforementioned outcomes was calculated as their surface under the cumulative ranking curve (SUCRA). The study quality was evaluated using the revised Cochrane risk-of-bias (RoB2) tool for randomized trials.

Results: After selection of studies, 9 RCTs were included in the systematic review.

On network meta-analysis for 'en-bloc' resection (9 RCTs, 872 patients, 5 techniques assessed), pocked with traction ESD (PT-ESD) (RR=1.02 - 95%CI=0.96-1.07) and pocket ESD (P-ESD) (RR=1.02 - 95%CI=0.98-1.05) showed higher efficacy, whereas hybrid ESD (H-ESD) (RR=0.94 - 95%CI=0.87-1.02) lower efficacy compared to conventional ESD (C-ESD).

On network meta-analysis for R0 resection (7 RCTs, 732 patients, 4 techniques assessed), PT-ESD (RR=1.05 - 95%CI=0.96-1.16) showed higher efficacy, and H-ESD (RR=0.97 - 95%CI=0.84-1.13) lower efficacy compared to C-ESD. Overall, P-ESD resulted the best technique for 'en-bloc' resection (SUCRA 0.70) and PT-ESD for R0 (SUCRA 0.83), while H-ESD showed the poorest performance for both outcomes (SUCRA 0.06 and 0.30, respectively) (Table 1).

On network meta-analysis for AEs (9 RCTs, 872 patients, 5 techniques assessed), PT-ESD (RR=0.35 - 95%CI=0.05-2.48) was associated with a lower

incidence of AEs, and H-ESD (RR=1.22 - 95%CI=0.30-5.01) with higher incidence of AEs, compared to C-ESD. Overall, PT-ESD resulted as the safest technique (SUCRA 0.83), followed by T-ESD (SUCRA 0.60), whereas H-ESD showed the poorest performance (SUCRA 0.28).

According to the RoB2 tool, none of the studies included was of poor methodological quality except for one.

'En-bloc'		R0		AEs	
P-ESD	0.70	PT-ESD	0.83	PT-ESD	0.83
PT-ESD	0.67	P-ESD	0.52	T-ESD	0.60
T-ESD	0.67	T-ESD	0.46	P-ESD	0.47
C-ESD	0.39	C-ESD	0.38	C-ESD	0.32
H-ESD	0.06	H-ESD	0.30	H-ESD	0.28

Table 1. SUCRA score ranking of different interventions in terms of 'en-bloc' resection rate, R0 resection rate and incidence of AEs.

Conclusion: The results of this network meta-analysis show a trend towards greater effectiveness and safety of PT-ESD for the removal of colonic lesions. H-ESD was associated with worse results and should be avoided, preferring other techniques.

Disclosure: Nothing to disclose.

Introduction: Resection of large non-pedunculated colorectal polyps (LNPCP) located in the rectum varies by institution and region with some, particularly colorectal surgeons, favouring TEM and others endoscopic resection (ER). There is a paucity of data directly comparing these strategies and the procedure of choice remains under debate. Our unit is a tertiary referral centre for complex polyps and early colorectal cancer. All rectal LNPCP were treated by TEM until a change in practice from 2011 when the first-line therapeutic strategy for rectal LNPCP changed to ER.

Aims & Methods: We aimed to report the outcomes of TEM and ER of rectal LNPCP from a large tertiary cohort. Large (≥20mm) rectal adenomas resected by TEM or ER (2009 – 2023) were analysed. From 2009-2011 all rectal adenomas were treated by TEM, after which the primary resection strategy changed to ER. Outcomes were compared between techniques. Given the difference in resection strategy, a composite outcome of septic complications included clinically significant perforation for ER (early or delayed perforation requiring any form of unplanned medical or surgical treatment) and septic complications for TEM (peritonitis or pelvic/anorectal sepsis).

Results: 704 rectal adenomas were resected by TEM (n=71), EMR (n=145) and ESD/Hybrid ESD (n=488) with a mean size of 45mm for TEM vs 55mm for ER (p<0.001). 100% of patients undergoing TEM required hospital admission vs 15% for ER (p<0.001), and 100% required general anaesthesia (GA) for TEM vs 26% for ER (GA or propofol sedation, p<0.001). En bloc resection was achieved for 96% of ESD resections, 54% of TEMs, 28% of EMR and 14% of hybrid ESD (p<0.001). The incidence of complications

were similar (9.9% for TEM versus 5.0% for ER, $p=0.10$). Recurrence occurred in 2.7% after ESD, 21.1% after EMR, 23.6% after Hybrid ESD and 36.4% after TEM ($p<0.001$). No patients undergoing ER or TEM required surgery as a result of a complication.

Conclusion: Despite significantly larger lesion sizes, ER in our institution provides far superior results for patients than TEM with relatively fewer patients requiring hospital admission and lower recurrence rates, especially with ESD. En bloc resection was more likely with ER as a result of the difficulty achieving en bloc resection for extremely large lesions with TEM, which can invariably be resected en bloc by ESD. These results have led to a policy of ER for all apparently benign rectal tumours regardless of size and, in recent years, ESD as the primary approach for all rectal lesions.

Introduction: Serrated polyps (SPs) are precursors to 15–20% of colorectal cancers (CRCs). However, there are uncertainties regarding which SPs require surveillance and at what intervals, with recommendations adapted from those for adenomas in the absence of solid evidence.

Aims & Methods: Our aim was to assess which SP risk characteristics relate to a higher risk of metachronous CRC or advanced polyps. We systematically searched PubMed, EMBASE, and Cochrane for cohort, case-control studies, and clinical trials from inception to Dec 31, 2023, for CRC or advanced polyps [advanced adenoma (AA) or advanced SP] incidence at surveillance stratified by baseline SP size, dysplasia, location, and multiplicity. CRC and advanced polyp incidence per 1,000 person-years (p-y) were estimated. We performed a meta-analysis by calculating pooled relative risks (RR) using a random-effects model.

Results: 5,903 studies were reviewed and 14 included, with 493,949 patients (mean age 59.5 years, 55% men). Mean follow-up was 4.9 years. CRC incidence per 1,000 p-y was 2.09 (95%CI 1.29–2.90) for advanced SP, 1.52 (0.78–2.25) for SP $\geq$ 10mm, 5.86 (2.16–9.56) for SP with dysplasia, 1.18 (0.77–1.60) for proximal SP, 0.52 (0.08–1.12) for $\geq$ 3SP, 0.50 (0.35–0.66) for non-advanced SP, and 0.44 (0.41–0.46) for normal colonoscopy. Metachronous CRC risk was higher in advanced SP vs non-advanced SP (RR 1.84, 95%CI 1.11–3.04), and vs normal colonoscopy (RR 2.92, 2.26–3.77); in SP $\geq$ 10mm vs <10mm (RR 2.61, 1.43–4.77), and vs normal colonoscopy (RR 3.52, 2.17–5.69); and in SP with dysplasia vs normal colonoscopy (RR 2.71, 2.00–3.67). No increase in CRC or advanced polyp risk was found in patients with proximal vs distal SP, nor in $\geq$ 3SP vs 1–2SP.

Conclusion: CRC risk is significantly higher in patients with baseline advanced SP after 4.9 years of follow-up, with risk magnitudes similar

to those described for AA, supporting the current recommendation for 3-year surveillance in patients with advanced SP.

Introduction: Although the prognosis of low-grade rectal neuroendocrine tumors (NET) is good, surveillance of patients with pathologically incomplete resection after endoscopic resection (ER) remains controversial.

Aims & Methods: This study aimed to evaluate the long-term outcomes of patients with grade 1 rectal NET after ER and the risk factors for incomplete resection. We retrospectively enrolled patients who were diagnosed with rectal NET grade 1 after endoscopic resection between January 2011 and December 2023. We divided the patients into two groups according to histopathological evaluation: complete resection and incomplete resection. Patients who were followed up for > 12 months were included in the analysis. Logistic regression analysis was performed to investigate the risk factors for incomplete resection after ER.

Results: In total, 454 patients were enrolled in this study. Mean (SD) lesion size was 5.7 (2.1) mm and lesion location (distance from anal verge) was 7.8 (3.1) cm from anal verge. The most common treatment method was endoscopic mucosal resection with strip biopsy method (EMR-S, n = 338, 74.4%). On histopathologic evaluation after ER, the complete resection rate was 80.6% (n = 366). Of the incomplete resections (n = 88, 19.4%), 82 (18.1 %) were margin positive and 11 (2.4%) were lymphovascular invasion. Mean follow up months were 38.8 (27.3) and 46.2 (30.2) months in entire patients and incomplete resection group, respectively. In logistic regress analysis showed the lesion size 5.1 – 10 mm (OR 1.9, 95% CI 1.021– 3.686, $P = 0.044$), multiple lesions (OR 8.9, 95% CI 1.454 – 71.165; $P = 0.021$), and retroflexion scope view (OR 4.3, 95% CI, 1.639 – 10.924; $P = 0.002$) were the independent risk factors associated with incomplete resection. During the follow-up period, despite the inclusion of patients with incomplete resection, no recurrence was observed.

Conclusion: Grade 1 rectal NET have a very good prognosis even with incomplete ER. Even if the resection is incomplete, progress can be observed without additional treatment.

Disclosure: Nothing to disclose.

Introduction: Delayed bleeding is a frequently observed complication after endoscopic mucosal resection of large adenomas of colorectum and duodenum. Even though the associated mortality is low, delayed bleeding causes significant morbidity and use of health care resources. Clip closure of the resection field reduces delayed bleeding, but it is time consuming and often complete closure is not achieved. Hemostatic gels and powders can be applied quickly and easily. These agents are in use for the treatment of active bleeding, but it is unknown, whether they will also prevent delayed bleeding when applied to the resection field prophylactically.

Aims & Methods: We conducted a randomized controlled trial of patients undergoing hot-snare endoscopic mucosal resection of flat lesion in the duodenum and colorectum at 15 centers in Germany. Lesions had to be non-pedunculated and measure at least 10 mm in the duodenum and 20 mm in the colorectum. Immediately after resection was completed patients were randomized to hemostatic gel application (intervention group) or no prophylaxis (control group). The primary endpoint was clinically significant delayed bleeding rate (CSDB) within 30 days after resection. Secondary endpoints included transfusion requirements, other complications, wound healing and lesion recurrence.

Results: A total of 233 patients were included in the trial. We performed a planned interim analysis when 200 patients were available for evaluation of the primary end point; at this point we stopped enrollment in the trial due to futility. Of the 200 patients included in the interim analysis, 100

(88 colorectal, 12 duodenal) were included in the intervention group and 100 (88 colorectal, 12 duodenal) in the control group. Groups were comparable in terms of patient age, sex, comorbidities, and lesion localization. CSDB occurred in 13 cases (13%) in the intervention group and in 6 cases (6%) in the control group. This difference was not statistically significant ($p=0.146$ Fisher's Exact Test). CSDB rates for colorectal lesions were 10% vs. 4.5% (intervention vs. control group) and for duodenal lesions 33% vs. 17%. Follow-up for patients already enrolled is continuing and data lock for the full study cohort is expected in May 2024. The full data set will be presented at UEG Week.

Conclusion: The application of a hemostatic gel following endoscopic mucosal resection of large non-pedunculated lesions in the duodenum and colorectum does not reduce the rate of CSDB.

Introduction: Endoscopic submucosal dissection (ESD) is emerging as the standard treatment for suspected superficial submucosal invasion lesions. Considering the global population ageing, understating the feasibility of this approach in elderly patients is of the utmost importance. Studies in this field have shown a tendency towards reduced resection rates and higher rates of complications.

Aims & Methods: We sought to assess the effectiveness and safety of colorectal ESD for patients aged ≥ 80 yo compared to 65-79 yo patients. We prospectively enrolled consecutive patients aged >64 years undergoing colorectal ESD between January 2019 and December 2023 from ten Italian Tertiary Referral Centres. Patients were classified as Elderly Group (E-Group, age >80 yo) and non-elderly group (NE-Group, 65-79 yo). Proce-

dures outcomes and adverse events were compared between E-Group and NE-Group and between patients with comorbidities and healthy (1-CM-Group and H-Group).

Results: A total of 980 patients were included [269 (27.5%) in the E-Group and 711 (72.5%) in the NE-Group]. Table 1 summarises the principal data and outcomes.

	Elderly group (n=269)	Non-elderly group (n=711)	p-value
Female sex, n (%)	120 (44.6)	311 (43.7)	0.81
Age (years), median (IQR)	83 (81-85)	72 (68-75)	<0.001
CCI, median (IQR)	5 (4-6)	3 (3-4)	<0.001
At least one comorbidity, n (%)	159 (59.1)	110 (15.4)	<0.001
Multiple comorbidities, n (%)	69 (25.7)	83 (11.7)	<0.001
General anaesthesia, n (%)	50 (18.6)	163 (22.9)	0.17
Procedure time (minutes), median (IQR)	90 (57-120)	90 (60-125)	0.66
Hospitalization, n (%)	202 (75.1)	541 (63.4)	0.001
En bloc resection, n (%)	250 (92.9)	673 (94.7)	0.30
R0 resection, n (%)	235 (87.4)	651 (91.6)	0.05
Length of hospital stay (days), median (IQR)	3 (2-4)	2 (2-4)	0.27
Sepsis, n (%)	2 (0.7)	5 (0.7)	0.95
Fever, n (%)	16 (5.9)	38 (5.3)	0.71
CRP increase, n (%)	16 (5.9)	50 (7.0)	0.55
PCT increase, n (%)	1 (0.4)	9 (1.3)	0.21
HF, n (%)	0	2 (0.3)	0.38
AKI, n (%)	1 (0.4)	3 (0.4)	0.91
Intraprocedural AEs, n (%)			
Perforation	10 (3.7)	46 (6.5)	0.10
Bleeding	16 (5.9)	32 (4.5)	0.35
Cardiovascular	2 (0.7)	1 (0.1)	0.13
Pulmonary	2 (0.7)	1 (0.1)	0.13
Pain	19 (7.1)	43 (6.0)	0.56
Drug-related	0	1 (0.1)	0.54
Postprocedural AEs (within 14 days), n (%)			
Perforation	1 (0.4)	6 (0.8)	0.43
Bleeding	6 (2.2)	36 (5.1)	0.05
Cardiovascular	0	2 (0.3)	0.38
Pulmonary	0	2 (0.3)	0.38
Delirium	6 (2.2)	1 (0.14)	0.001
Systemic infections	3 (1.1)	12 (1.7)	0.51

En-bloc resection and R0 rate did not statistically differ ($p=0.30$; $p=0.05$) between E and NE-Groups. Oncological curative resection was achieved in the two groups without significant differences ($p=0.41$). Histological outcomes were comparable between the two groups, except for lymphovascular invasion [E:14 (5.2%) vs NE:14 (2.0%); $p=0.007$ – OR:2.9 (CI:1.3-6.6)]. Regarding clinical course, intraprocedural and 14 days-adverse events (AEs), no statistically significant differences were found between the two groups, except for a higher rate of post-procedure delirium in the E-Group [6 (2.2%) vs 1 (0.1%); $p=0.001$ –OR:16.2 (CI:1.9-135.2)]. 1-CM-Group showed a higher rate of intraprocedural bleeding ($p=0.001$), fever onset ($p<0.001$), C-reactive protein ($p=0.006$) and procalcitonin increase ($p=0.02$), delayed perforation ($p=0.03$) and systemic infections ($p=0.02$) compared to the H-Group. The presence of one or more comorbidity, but not the age, was associated with a poorer clinical course [$p<0.001$; OR:2.3 (CI:1.5-3.6)] and poor overall course (poor clinical course combined with 14 days AEs) [$p<0.001$; OR:2.1 (CI:1.4-3.0)]. ASA classification (OR: 1.36; CI:1.01-1.83), the presence of one comorbidity (OR: 1.73; CI:1.14-2.63), and procedure time (OR: 1.01; CI:1.00-1.01) were poor outcome predictors. After excluding patients with at least one comorbidity, still no differences in terms of poor overall course ($p=0.21$) were registered between E and NE-Group.

Conclusion: Colorectal ESD is an effective and safe procedure in elderly patients. Physicians should acknowledge delirium as a possible AE in patients aged over 80. The presence of comorbidities should drive the execution of a comprehensive pre-procedural assessment and post-procedural care, to optimize outcomes and minimize complications.

Disclosure: Nothing to disclose.

Introduction: Endoscopic resection (ER) techniques for treating large non-pedunculated colorectal polyps (LNPCP) have advanced significantly and the relevance of early studies reporting outcomes may diminish with time. EMR remains the predominant therapeutic option for LNPCP in western practice, but ESD is increasingly employed. Limited studies demonstrate safety and efficacy for highly selected patients, but no studies examine the practical introduction of ESD (which has a steep learning curve) as a standard component of ER strategies in real-world practice.

Aims & Methods: Patients with LNPCP treated by ER at a tertiary referral centre between January 2011 and September 2023 were included. ERs were divided into 2 time periods (Period 1: January 2011 – May 2018 and Period 2: June 2018 – September 2023). Resection technique and outcomes including en bloc resection, successful single-session resection and complications were compared for procedures between Period 1 and Period 2.

Results: 1563 LNPCP were treated with ER over the study period. ER was successful in 1517 (97%). The mean lesion size was 46.9mm +/- 26.3mm (median 40mm, range 20mm–210mm). 774 LNPCP were resected using EMR/pEMR and 743 by ESD/Hybrid ESD. ESD was used to resect 476 (64%) LNPCP during Period 2 compared to 267 (34.7%) during Period 1 ($p<0.001$). Whilst introducing ESD into practice during Period 1, a combination of Hybrid ESD and ESD were used with an en bloc resection rate of 64%, but en bloc resection for ESD increased to 98% during Period 2 ($p<0.001$). 97% of rectal LNPCP were resected by ESD during period 2 compared to 62% during period 1 ($p<0.001$). 45% of colonic LNPCP were resected by ESD during period 2 compared to 17% during period 1 ($p<0.001$). Complications occurred less frequently in Period 2 compared to Period 1 (2.9% versus 5.1%, $p=0.04$) and there was no difference in the rate of clinically significant perforation (1.2% versus 1.0%, $p=0.76$) or post-procedure bleeding (1.5% versus 1.6%, $p=0.89$). Fewer patients were admitted to hospital during period 2 compared to period 1 (5.6% versus 14.8%). Training occurred more frequently in Period 2 with 258 (35%) ERs performed in part or completely by an endoscopy fellow compared to 126 (16%) in period 1. 105 (22%) ESDs were performed in part or completely by an endoscopy fellow during Period 2 compared to 30 (11%) during period 1.

Conclusion: These data demonstrate the evolving nature of endoscopic resection practice in modern advanced practice. Large volume ESD can safely be incorporated into standard practice with a near-exclusive policy of ESD to treat all rectal LNPCP and nearly half of colonic LNPCP resected by ESD. En bloc resection rates comparable to Japanese expert centres can be achieved with no effect on complications. Moreover, regular training in ESD can safely be introduced.

Disclosure: Nothing to disclose.

LATE FIRST ENDOSCOPIC SURVEILLANCE FOLLOWING PIECEMEAL
ENDOSCOPIC MUCOSAL RESECTION OF LARGE COLORECTAL POLYPS IS
NOT ASSOCIATED WITH INCREASED ADENOMA RECURRENCE

T. Arraf¹, Y. Gorelik¹, F. Mazzawi¹, S. Banna², R. Moalem², A. Klein¹

Gastroenterology, Nazareth, Israel

Contact E-Mail Address: yurigorelik@gmail.com

Introduction: Piecemeal endoscopic mucosal resection (pEMR) is the preferred treatment for large non-pedunculated colorectal polyps (LNPCPs) [1,2]. A major limitation of pEMR is residual or recurrent adenoma (RRA), which was reported to in 15%-30% of cases at first surveillance colonoscopy (SC1)[3], performed 3-6 months after the index procedure, but is reduced to the range of 3%-5% by applying ablative measures to the post-EMR resection margin[4].

Aims & Methods: This study aimed to evaluate the effects of late SC1 on RRA.

This is an analysis of a prospectively collected cohort of adult patients referred for pEMR at two academic centers in Israel, from 2016 to 2023. We included all patients who underwent pEMR of LNPCPs and completed SC1.

We compared outcomes between patients who completed early SC1 at 3-6 months following the index procedure with patients who completed late SC1 later than 6 months. All procedures and surveillance colonoscopies were performed by experienced endoscopists trained in pEMR using high-definition scopes. EMR was followed by thermal ablation of the entire mucosal defect margin with snare soft tip coagulation, as previously described[4].

Scar evaluation at SC1 was performed with high-definition white light and chromoendoscopy. Our primary endpoint was RRA at SC1.

Analyses were performed per lesion. We compared baseline parameters and outcome rates between groups, and performed multivariate analysis to assess the adjusted association of months to SC1 with RRA.

Results: We analyzed 516 lesions that underwent index pEMR resection and subsequent SC1. Baseline parameters and recurrence rates are presented in Table 1. The early SC1 group (n=371) underwent SC1 at a mean of 5.1 months versus a mean of 11.1 months in the late SC1 group (p<0.01; Table 1). Polyp size in the early SC1 group was significantly larger than that in the late SC1 group (mean size 35.9 mm [SD 13.9] vs. 32.1 mm [SD 12.4], p<0.01; Table 1). The distribution of lesion location, granularity differed between the groups (Table 1). However, there were no significant differences in lesion Paris classification or rates of high grade dysplasia (Table 1).

	Early SC1 (n=371)	Late SC1 (n=145)	P value
Time to SC1, months	5.1 (1.1)	11.1 (5.6)	<0.01
Age, years	65.4 (10.4)	68.0 (10.2)	0.01
Female, n (%)	168 (45.4)	51 (35.2)	0.05
Lesion Size, mm	35.9 (13.9)	32.1 (12.4)	<0.01
Distal location, n (%)	111 (29.9)	29 (20.0)	0.03
Granular morphology, n (%)	230 (63.7)	74 (53.2)	0.04
Paris IIb/IIc/III, n (%)	39 (10.5)	15 (10.3)	1.00
High grade dysplasia, n (%)	97 (26.1)	33 (22.8)	0.49
Recurrence at SC1, n (%)	23 (6.2)	7 (4.8)	0.70

Table 1. Comparison of baseline variables and outcome between the early and late SC1.

SC1, First surveillance colonoscopy.

We found no statistically significant difference in the rate of recurrence at SC1 between the two groups (6.3% in the standard group versus 4.8% in the delayed group, p=0.64). Additionally, a sub-analysis comparing the

early SC1 group to patients with very late SC1 (>12 months – mean time to SC1 17.9 (SD [5.4] months) and did not reveal significant difference in recurrence at SC1 (6.2% in the early SC1 vs 6.3% in the very late group, p=1). Multivariate analysis, adjusted for lesion size, location, and high-grade dysplasia, showed that time to SC1 was not significantly associated with RRA (odds ratio 1.05, 95% confidence interval 0.98-1.13).

Conclusion: Late SC1 is not associated with an increased RRA. Hence, we suggest that high-quality pEMR with margin ablation may alleviate the need for early SC1, thereby reducing healthcare and patient burdens. Further interventional studies are required.

IMPACT OF MARGIN THERMAL ABLATION AFTER ENDOSCOPIC
MUCOSAL RESECTION OF LARGE (≥20MM) NON-PEDUNCULATED
COLONIC POLYPS ON LONG TERM RECURRENCE

T. O'Sullivan^{1,2}, F.V. Mandarino¹, J. Gauci¹, A. Whitfield^{1,2}, C. Kerrison¹, C. Nascimento¹, S. Gupta^{1,2}, O. Cronin^{1,2}, A. Sakiris¹, J.F. Prieto Aparicio¹, S. Arndtz³, G. Brown³, S. Raftopoulos⁴, D.J. Tate⁵, E. Lee¹, S. Williams¹, N. Burgess^{1,2}, M.J. Bourke^{6,2}

Introduction: EMR is the standard of care for the management of large (≥20mm) non-pedunculated colonic polyps (LNPCPs). However, its efficacy and cost effectiveness, are limited by recurrence and the necessity for scheduled surveillance. Consequently, current surveillance intervals are conservative. Margin thermal ablation (MTA) after EMR for LNPCPs has dramatically reduced the incidence of recurrence at first surveillance colonoscopy at six-months (SC1). If this effect is durable, then subsequent surveillance intervals in patients who have been cleared of synchronous polyps could be substantially lengthened. We prospectively evaluated long-term surveillance outcomes in a cohort of LNPCPs that have undergone MTA.

Aims & Methods: Consecutive patients with LNPCPs undergoing EMR and MTA from four academic endoscopy centres were prospectively recruited. All patients that underwent successful endoscopic resection received

SC1 six months post resection. EMR scars were carefully evaluated with high-definition white light, narrow band imaging with near focus and biopsy. In the absence of recurrence, second surveillance (SC2) colonoscopy was conducted at a subsequent interval of 12 months with the scar evaluation process repeated. The primary outcome was recurrence at SC2 in all LNPPCs with a recurrence-free scar at SC1.

Results: 1324 LNPPCs referred for EMR were enrolled over 90 months until October 2022. Following exclusions, 1163 LNPPCs underwent EMR with complete MTA. 856 LNPPCs underwent SC1. 32 additional synchronous LNPPCs were cleared at this procedure. 25/856 (2.9%) (95%CI 1.9-4.3%) LNPPCs demonstrated recurrence. 469 LNPPCs free of recurrence at SC1 (median size 35mm) underwent SC2 at a mean interval of 22.9 months (95%CI 21.9-23.95) after the index EMR. 468 demonstrated a bland scar without recurrence. Only one recurrence occurred (0.2% 95%CI 0-1.2%), related to a 0-IIa+Is 20mm granular TVA located on the ileocaecal valve.

Conclusion: LNPPCs that have undergone successful EMR with MTA and are free of recurrence at SC1 are very unlikely to develop recurrence in subsequent surveillance out to 2 years. Following EMR of LNPPCs with MTA, patients who are cleared of synchronous neoplasia and demonstrate no recurrence after careful scar examination, can potentially undergo next surveillance in 3-5 years. Such an approach would reduce costs and enhance patient compliance.

Introduction: Colorectal endoscopic submucosal dissection (ESD) is spreading worldwide, with increasing demand for training. Standardized skills assessment has yet to be defined to guarantee the quality and safety of the results obtained by trainees during their learning curve. ESGE recommends that the first ESD procedures should be supervised by an ESD-proficient endoscopist. The impact of a trainee's active participation on these initial supervised ESD results should be addressed.

The first ESD procedures are recommended to be performed under the supervision of an endoscopist with ESD expertise as advised by the European Society of Gastrointestinal Endoscopy (ESGE). The impact of active participation of a trainee on the outcome of these initial supervised ESDs should be investigated.

Aims & Methods: Between 01/2017 and 01/2024, all consecutive colorectal ESD procedures were prospectively registered by 3 participating ESD training centers, and data were analyzed retrospectively. Trainee participation was tracked. A trainee was defined as having performed less than 50 ESD's on humans, alone or under supervision. We compared the main procedural outcomes with respect to the presence or absence of a trainee

involved in the colorectal ESD procedure. Multivariate analysis and propensity score matching (PSM) were performed.

Results: 2462 consecutive colorectal ESD were included, of which 543 procedures (22%) involved the active participation of a trainee (15 trainers/15 trainees). Rectal lesions were more often treated with participation of a trainee (56% vs 31%, $p<0.001$ *with-trainee vs trainer-alone* respectively). There was no significant difference in en-bloc, R0 and curative resection rates whether a trainee participated or not (95.8%, 85.9% and 84.9% vs 95.1%, 88.2% and 84.7%, *with-trainee vs trainer-alone* respectively). Participation of a trainee resulted in a significant decrease in dissection speed (29.4 mm²/min vs 43.9 mm²/min, $p<0.001$ *with-trainee vs trainer-alone* respectively). Rates of perforation, delayed bleeding and surgery for complications were 8.6%, 5.9% and 0.9% vs 9%, 4.5% and 0.7% for *with-trainee vs trainer-alone* respectively, without significant differences. After PSM, the presence of a trainee significantly decreased the dissection speed (29.4 mm²/min vs 42.7 mm²/min, $p<0.001$ *with-trainee vs trainer-alone* respectively), increased the perforation rate (8.7% vs 5%, $p=0.023$ *with-trainee vs trainer-alone* respectively), but did not influence the curative resection rate (84.9% vs 88.8%, $p=0.078$ *with-trainee vs trainer-alone* respectively).

Conclusion: Active participation of a trainee during colorectal ESD did not affect the curative resection rate. However slower dissection speed and higher perforation rates, without increasing the need for surgery, were observed.

THE PREDICTIVE ROLE OF AMMONIA IN LIVER-RELATED DECOMPENSATION AND MORTALITY IN PATIENTS WITH ADVANCED CHRONIC LIVER DISEASE

J. Damasceno e Costa¹, L. Andrade², T. Carvalho¹, A. Guimarães¹, J. Neves¹, R.S. Costa¹, D. Costa¹, A.C. Caetano¹, R. Gonçalves¹

Introduction: Advanced chronic liver disease (ACLD) may present in different stages with distinct prognoses. Child-Pugh and MELD scores are commonly used models for predicting liver-related mortality and decompensation, but they have several limitations.

An alternative or complementary tool that is simple and cost-effective would be invaluable. Recently, some studies identified a potential role of ammonia in predicting liver-related outcomes.

Aims & Methods: Our primary objective was to explore the predictive role of plasma ammonia levels regarding liver-related complications and mortality. Our secondary aim was to validate a new measure that corrects baseline ammonia levels to the upper limit of normal (AMM-ULN) and test a cut-off which was proposed in the literature to define patients at higher risk of such outcomes (AMM-ULN ≥ 1.4).

This retrospective study included 278 patients with ACLD who had an ammonia measurement in our hospital between 2018 and 2022. ACLD patients were divided into compensated and decompensated stages, with the latter being subdivided into three stages, according to the type of decompensation. Outcomes of liver-related decompensation and mortality were assessed in each group. AMM-ULN was evaluated as a predictor of these outcomes both in compensated and decompensated patients. The predictive accuracy of AMM-ULN was then determined by identifying the best cut-off.

Results: Plasma ammonia levels and AMM-ULN were predictors of hepatic decompensation (HR = 1.453, 95%CI 1.085 – 1.945, $p = 0.012$) and mortality (HR = 1.010, 95%CI 1.003 – 1.017, $p < 0.001$) at 12 months, in the compensated patient group. The AUROC for AMM-ULN was 67.4% in 1-year decompensations and 69.5% in 1-year mortality, with similar results for ammonia levels. AMM-ULN ≥ 1.4 identified patients at higher risk of liver-related decompensation and mortality at 12 months ($p = 0.009$ and $p = 0.020$, respectively).

Conclusion: Both ammonia levels and AMM-ULN were predictors of hepatic decompensation and liver-related mortality in compensated patients, at 12 months of follow-up. AMM-ULN ≥ 1.4 identified patients at higher risk of liver-related decompensation and mortality at 12 months.

Introduction: Subjects with chronic liver disease have shown higher circulating ethanol levels after fasting or carbohydrates ingestion. However, clinical functional data about the capability of the injured liver to cope with alcohols remain limited.

In this study we used exhaled breath analysis to explore the conversion of an alcohol to the corresponding ketone, and a ketone to the corresponding alcohol, to establish the suitability of potential metabolic alterations and identify subjects with cirrhosis using a non-invasive breath test.

Aims & Methods: 2-butanol, and 2-pentanone (the substrates) were selected as an alcohol and a ketone based on their safe profile for human consumption, their reported hepatic metabolism, and their presence in breath. Hepatic metabolism was confirmed by simultaneous treatment of human suspension hepatocytes with 10 ng/ μ l of 2-butanol, and 2-pentanone to measure their conversion to respectively 2-butanone, and 2-pentanone (the bioproducts) by using headspace analysis coupled with gas-chromatography mass-spectrometry (GC-MS). Clinical metabolism of these compounds was evaluated by measurement of the breath profile in 14 subjects with cirrhosis and 14 healthy controls before and at different timepoints (10 - 120 minutes) after simultaneous ingestion of 2-butanol (100 mg) and 2-pentanone (100 mg) using Breath Biopsy® OMNI.

Results: The bioproducts were present in the head space of primary hepatocytes treated with the substrates and absent in control conditions omitting primary hepatocytes or substrates. After an overnight fasting all the participants showed breath levels of investigated compounds with no differences between healthy and cirrhosis groups ($p > 0.05$). After ingestion of the substrates, all the subjects showed a > 100 -fold increase of investigated compounds within 10 minutes. Subjects with cirrhosis showed higher levels of 2-butanone and 2-pentanone ($p < 0.05$) compared to healthy controls between 20- and 90-minutes post-administration. An exploratory classification model built on these breath-induced biomarkers at 20 minutes showed an area under the ROC curve of 0.92.

Conclusion: 2-butanol and 2-pentanone are metabolized to the corresponding ketone and alcohol in primary hepatocytes, supporting previous findings reporting hepatic metabolism. Subjects with cirrhosis showed higher breath levels of secondary alcohols independently from administration of the alcohol or the corresponding ketone, suggesting that the hepatic function is more balanced toward the alcohol production compared to healthy controls. This metabolic adaptation may contribute to higher circulating ethanol levels observed in subjects with chronic liver disease and be exploited in a breath test for cirrhosis detection.

A NONINVASIVE AND EFFECTIVE STRATEGY TO QUANTIFY ESOPHAGEAL VARICES FOR MONITORING AND STRATIFYING BLEEDING RISK IN PATIENTS WITH PORTAL HYPERTENSION USING ARTIFICIAL INTELLIGENCE-ASSISTED CONTRAST-ENHANCED CT

J. Liu¹, K. Liao², J. Yang¹, K. Deng¹

Contact E-Mail Address: cqjlh1004@163.com

Introduction: Esophageal variceal bleeding is a serious and fatal complication of cirrhosis. Currently, efficient noninvasive monitoring strategies are lacking. By applying artificial intelligence (AI) to computed tomography (CT) imaging, we developed an innovative tool to meet clinical needs.

Aims & Methods: This is an ambispective cohort study conducted at West China hospital between April 2021 and December 2021, patients underwent endoscopy and enhanced CT were registered. Furthermore, 97 patients with radiomic and hepatic venous pressure gradient data were enrolled from a portal hypertension database. High-risk esophageal varices (HREV) were defined as either moderate-severe varicose (HREV-1) or EV requiring intervention (HREV-2). Deep learning was used to develop segmentation and EV quantification models. The EV bleeding prediction model was established using least absolute shrinkage and selection operator (LASSO) regression and logistic regression analysis. The area under the curve (AUC) was calculated for efficiency evaluation. This trial is registered with the Chinese Clinical Trial Registry (ChiCTR2300069865) and is completed.

Results: A total of 2291 patients in the retrospective (n=780) and prospective (n=1511) cohorts were included. The internal and external validation cohort AUCs were 0.976 and 0.951 for EV vs. non-EV, 0.986 and 0.951 for HREV-1, and 0.978 and 0.898 for HREV-2, respectively. We found that volume ($p=0.0348$) and AI-10 ($p=0.0196$) were closely related to portal pressure. We further analyzed the AI features and bleeding events for patients with cirrhosis in the retrospective (n=254) and prospective (n=569) cohorts and applied the EV bleeding prediction model (validation cohort AUCs of 0.669, 0.701 and 0.705 at 1, 3, and 6 months, respectively), which was not inferior to that of endoscopic signs ($p > 0.05$).

Conclusion: Enhanced CT assisted by AI is a promising noninvasive strategy for quantifying EV, recognizing HREV and predicting short-term bleeding risk and has the potential to replace simple gastroscopy for diagnosis or monitoring. This approach could decrease unnecessary gastroscopy to some extent.

Introduction: Liver cirrhosis is a late stage of liver fibrosis characterized by progressive deterioration of liver function, leading to potentially life-threatening complications. Recent studies focusing on bacterial alterations of gut microbiota have shown their association with liver disease pathogenesis, decompensation, and hospitalization rates. Recently, there has been increasing recognition of the potential role of gut fungal changes in liver cirrhosis, however, further investigation in this field is warranted.

Aims & Methods: The aim of this study was to determine gut fungi composition changes in patients with liver cirrhosis and to assess whether these changes are related to liver disease severity. For the analysis were used DNA samples, extracted from the liver cirrhosis patients' and healthy controls' stool samples. Internal transcribed spacer (ITS) was amplified and sequenced using MiSeq Illumina sequencing machine. Bioinformatical and statistical analysis were performed to reveal the fungal profile of each study group.

Results: Forty-five patients with liver cirrhosis and 45 healthy controls were included in the study. No significant differences in age or gender were observed between the cirrhosis and control groups. Cirrhosis patients showed significantly reduced fungal richness compared to the control cohort. However, no difference was observed in the Shannon alpha diversity index. No significant alterations in fungal compositions were noted concerning gender and etiology within the cirrhosis group. Patients who had Child-Pugh B and C liver cirrhosis had a significant shift in stool fungi composition compared to those in the Child-Pugh A group. Patients with Child C liver cirrhosis had a significantly increased fungi abundance compared with the Child A group. In accordance with the MELD score, patients with score ≥ 15 , had significantly increased richness and fungal diversity. Furthermore, an elevated abundance of the *Candida* genus was observed in liver cirrhosis patients group, while *Saccharomyces* genus was increased in the control group.

Conclusion: Patients with liver cirrhosis had reduced richness in stool fungal composition and an increased abundance of the *Candida* genus when compared with healthy controls. Moreover, patients with worse liver function had significant shifts in fecal fungal composition, suggesting that fungal alterations may be associated with cirrhosis progression.

HIGH PREVALENCE OF CHOLELITHIASIS AND ASYMPTOMATIC GALLBLADDER WALL THICKENING IN PATIENTS WITH CIRRHOSIS

A. Protopapas¹, A. Tsankof¹, V. Kyritsi¹, C. Gogou¹, M. Kyziroglou¹, E. Papathanasiou¹, C. Chatzikosma¹, A. Michalopoulos¹, C. Savopoulos¹, A. Protopapas¹

¹Aristotle University of Thessaloniki, AHEPA University Hospital, First Propedeutic Department of Internal Medicine, Thessaloniki, Greece

Contact E-Mail Address: adoprot@hotmail.com

Introduction: Patients with cirrhosis have been shown to have an increased risk of developing gallstones. Simultaneously, gallbladder wall thickening constitutes a frequent accidental finding in patients with cirrhosis undergoing imaging studies.

Aims & Methods: Our study aimed to determine the frequency of cholelithiasis and asymptomatic gallbladder wall thickening in a population of hospitalised patients with cirrhosis. Consecutive hospitalised patients with cirrhosis who underwent imaging studies (ultrasound, computed tomography or magnetic resonance imaging) were prospectively enrolled. Patients with symptoms suggestive of acute biliary disease or biliary etiology of cirrhosis were excluded. Gallbladder wall thickening was defined as measurements > 3mm.

Results: A total of 128 patients were included. Patients had a mean age of 64 ± 12.2 years and were predominantly male (73.4%) and with decompensated liver cirrhosis (DeCi) (78.1%). Alcohol-associated liver disease (47.7%) and metabolic dysfunction-associated steatohepatitis (16.4%) were the leading causes of cirrhosis. Most patients were classified as Child-Pugh stage B (53.1%), followed by patients in stage C (32%) and stage A (14.8%). A significant percentage of the patients had cholelithiasis (39.8%), with DeCi patients being more likely to have gallstones (45%) than compensated patients (21.4%) (p=0.024). Furthermore, a significant number of patients had asymptomatic gallbladder wall thickening (32.8%), with almost half of them (42.9%) not concurrently having cholelithiasis. Patients with DeCi were significantly more likely to have gallbladder wall thickening (39%) than patients with compensated disease (10.7%) (p=0.005). There was no statistical correlation between etiology of cirrhosis and cholelithiasis or gallbladder wall thickening.

Conclusion: Patients with cirrhosis maintain a significant probability of developing gallstones while also frequently displaying gallbladder wall thickening in the absence of acute biliary disease. Clinicians should keep in mind the possibility of biliary complications in these patients while simultaneously refraining from rushing to a diagnosis of acute cholecystitis based on imaging alone.

Disclosure: Nothing to disclose.

Introduction: Hepatic encephalopathy (HE) is a group of neuropsychiatric disorders caused by liver dysfunction or portosystemic shunting, and it is a common complication in the progression of liver cirrhosis. Pathophysiologically, there is an imbalance between the hepatic production and clearance of ammonia, leading to an increase in serum ammonium levels, which can lead to neurological dysfunction, intracranial hypertension, cerebral oedema and ultimately death (1).

There are multiple triggering factors; one of the most well-known is upper gastrointestinal bleeding (UGIB) (2). Therefore, we suggest that the coexistence of UGIB and HE is associated with an increased risk of in-hospital mortality and prolonged hospital stay. This study aims to analyse the risk factors for HE during an episode of UGIB and its impact on the patient's prognosis.

Aims & Methods: Retrospective analysis of a prospective registry of patients with UGIB treated at the Hospital Universitario Virgen de las Nieves (2013-2022). Statistical analysis was performed using R v4.3.2. Categorical variables were compared using the Chi-square or Fisher's exact test. Odds ratios (OR) and 95% confidence intervals (95%CI) were calculated using the Woolf-Haldane formula for significant variables. Continuous variables were assessed using the Shapiro-Wilk test for normality, and Levene's test was used to check for homogeneity of variances. The t-test for independent samples, with or without Welch's correction, and the Mann-Whitney U test were used for hypothesis testing. Multivariate analysis is performed to identify independent risk factors for variables with statistically significant differences, calculating Odds Ratios (OR) and their 95% confidence intervals (95%CI).

Results: A total of 343 patients with liver cirrhosis and UGIB were analysed, of whom 260 were male and 83 were female, with an overall mean age of 61.51 ± 12.38, developing HE in a total of 66 patients. After comparing the cirrhotic population that developed HE with those that did not, we observed a series of variables that correlated significantly, as shown in Table 1.

Hepatic encephalopathy	Present (means ± STD) N= 66	Missing (means ± STD) N= 277	P-value
Bilirubin	4,78 ±7,7	2,18 ± 3,24	0,000015
Albumin	2,63 ± 0,57	3,04 ±1,28	0,000056
INR	1,77 ± 0,62	1,65 ±0,82	0,0056
Creatinine	1,37 ± 0,7	1,6 ± 6,41	0,0036
Platelets	125945 ±72209	140502 ±94082	0,66
Ascites	48,07%	29,12%	0,015
Urea	95,72 ±57,69	70,53 ±42,63	0,00017
Days of admission	11,75 ± 12	10,43 ±12,22	0,32
Mortality rate	33%	16%	0,00016

Subsequently, after performing multivariate analysis, we noticed that only

four variables had a significant independent relationship: bilirubin with an OR (95% CI) of 1.07 (1-1.16) with $p=0.064$; albumin with an OR (95%CI) of 0.41 (0.23-0.7) with $p=0.0017$; ascites with an OR (95%CI) of 1.65(1.01-2.71) with $p=0.04$; and urea on admission with an OR (95% CI) of 1.01 (1-1.102) with $p=0.0005$.

Conclusion: We conclude that patients with cirrhosis admitted for UGIB and who develop HE have higher mortality rates during admission without an apparent increase in hospital stay. Our study indicates that bilirubin, albumin, ascites, and urea are the most accurate predictors of HE development. These findings aligns with Rattanasupar et al. (2), concluding that the Child-Pugh score, which also considers the abovementioned variables, best predicts hepatic encephalopathy after UGIB. Further research is necessary to explore additional risk factors that aid in predicting and modelling the disease based on our findings.

OUTCOMES AND RISK FACTORS OF EARLY LIVER INJURY AFTER TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

X. Wang¹, B. Kunyi¹, X. Luo¹

¹Sichuan University West China Hospital, Department of Gastroenterology and Hepatology, Chengdu, China

Contact E-Mail Address: xiaoze.wang@foxmail.com

Introduction: Transjugular intrahepatic portosystemic shunt (TIPS) reduces the portal vein blood flow into the liver while declining portal venous pressure, resulting in liver ischemia injury and even liver failure.

Aims & Methods: This study aimed to verify the impact of the post-TIPS early liver injury on survival through large sample retrospective analysis and explore the risk factors of post-TIPS liver injury. The data of patients undergoing TIPS in West China Hospital from November 2009 to March 2021 were collected. We analysed the predictive ability of end-stage liver disease model score (MELD) on the 90-day, 1-year and 3-year survival rates after TIPS and screened out the independent predictive factors of post-TIPS liver injury by regression analysis.

Results: A total of 1108 patients were included. The post-TIPS MELD score was superior to other scoring systems, with a better predictive effect on the 90-day survival rate and 1-year survival rate. The 90-day survival rate (98.3% vs. 87.2%, HR 15.9, 95% CI 7.9-31.9, $P < 0.001$), 1-year survival rate (95.1% vs. 79.2%, HR 8.3, 95% CI 5.0-13.7, $P < 0.001$) and 3-year survival rate (86.5% vs. 68.8%, HR 4.0, 95% CI 2.8-5.7, $P < 0.001$) were significantly higher in patients with a post-MELD score less than 15. Preoperative total bilirubin, serum creatinine, INR and change of portosystemic pressure gradient were independent predictors of early liver injury after TIPS.

Conclusion: Baseline liver function and pressure reduction contribute to the occurrence of early liver injury after TIPS. Post-TIPS MELD score can accurately predict short-term and long-term survival.

Disclosure: Nothing to disclose.

SAFETY STATINS IN CIRRHOTIC PATIENTS WITH AN INDICATION FOR HIGH CARDIOVASCULAR RISK. RETROSPECTIVE COHORT

R.T. Hernández Rodríguez¹, M.G. Reyes Zermeno¹

¹Instituto de Seguridad y Servicios Sociales de los Trabajadores del Estado, Ciudad de México, Mexico

Contact E-Mail Address: roxana28t@gmail.com

Introduction: Cirrhosis is a chronic condition with a high mortality. Cirrhotic patients with portal hypertension frequently present with large esophageal varices with bleeding or need for endoscopic intervention. The choice of treatment for variceal hemorrhage is endoscopic ligation and beta-blockers, which can be used as secondary prophylaxis. The pleiotropic effects of statins have been reported for the treatment of cardiovascular diseases, but at the liver level they favor the reduction of the hepatic venous pressure gradient (HVPG), with a decrease in the number of variceal hemorrhage events; however, their use had been restricted in cirrhotic patients due to their association with elevations in liver biochemistries.

Aims & Methods: To evaluate the safety statins in cirrhotic patients with an indication for high cardiovascular risk. And as a secondary aim, determine the presence of variceal hemorrhage during follow-up. This retrospective cohort study was carried out by the "Centro Médico Nacional 20 de Noviembre" between 2018 to 2022. Child Pugh A and B cirrhotic patients with a history of variceal hemorrhage or large varices with endoscopic ligation intervention without active hemorrhage were included and observed over a period of 4 years. To determine adverse events, compatible clinical data and biochemical examinations were searched in the electronic record, and pharmacovigilance committee records were reviewed.

Characteristics	Statin treatment, % (n=53)	Without statin treatment, % (n= 53)	p
Sex			
Female	58.5 (31)	58.5 (31)	
Male	41.5 (22)	41.5 (22)	
Etiology			
MAFLD	11.3 (6)	15.1 (8)	
PBC	11.3 (6)	17 (9)	
AIH	9.4 (5)	13.2 (7)	
HCV	22.6 (12)	20.8 (11)	
HBV	1.9 (1)	1.9 (1)	
ALCOHOL	13.2 (7)	11.3 (6)	
CRYPTOGENIC	30.2 (16)	20.8 (11)	
Age (years)	63	61	0.320
Aspartate aminotransferase(U/L)	39.6	61	0.001
Alanine aminotransferase(U/L)	37.6	51.2	0.041
Albumin	3.8	3.6	0.045
Prothrombin time	12.7	14	0.002
Total cholesterol (mmol/L)	157.6	179.4	0.042
International normalized ratio	1.06	1.1	0.004

Table 1. Demographics, selected clinical characteristics, and outcomes of patients..

Results: A total of 106 patients were included, of which 53 with statin use and 53 without statins. The characteristics were 41.5% men (n=44), 58.5% women (n=62). The average age was 62 ± 10 years. In order of frequency, the causes were: cryptogenic 25.5% (n=27), hepatitis C virus (HCV) 21.7% (n=23), primary biliary cholangitis (PBC) 14.2% (n=15), metabolic dysfunction-associated fatty liver disease (MAFLD) 13.2% (n=14), alcohol 12.3% (n=13), autoimmune hepatitis (AIH) 11.3% (n=12), hepatitis B virus (HBV)

1.9% (n= 2). With Child Pugh A 67% (n=71) Child Pugh B 35% (n=33). In the statin and non-statin group, the average values of the following variables were PT 12.7 ±1.9 vs 14 ±2.2, AST 39.6 ±24 vs 61 ±40, ALT 37.6 ±28 vs 51 ±38, albumin 3.8 ±0.6 vs 3.6 ±0.5, total cholesterol 157.6 ±35 vs 179.4 ±68, INR 1.06 ±0.17 vs 1.1 ±0.18 (p< 0.05) (Table 1). In the group of patients with statin use in 18.4% (n=10) Variceal ligation was performed, and in the group without statins, 24.5% (n=13), with a RR of 1.075, 95% CI (0.8-1.3). In the group of patients with statin use, 9.5% (n=5) had a bleeding event, and in the group without statins, 7.5% (n=4) had a bleeding event, with an RR of 1.25, CI 95% (0.3-4.4). None of the participants had clinical adverse effects.

Conclusion: The use of statins in cirrhosis compensated with portal hypertension was safe. In this study we could not demonstrate the pleiotropic effect of statins, probably due to the sample size. Therefore, it is necessary to generate subsequent studies including a larger number of patients.

Disclosure: Nothing to disclose.

PROTON PUMP INHIBITORS IN CIRRHOTIC PATIENTS: ARE THEY A RISK FACTOR FOR SPONTANEOUS BACTERIAL PERITONITIS?

S.Ş. Juncu^{1,2}, H. Minea^{1,2}, E.C. Cojocariu^{1,2}, A. Trifan^{1,2}, A.-M. Sîngeap^{1,2}
¹University of Medicine and Pharmacy "Grigore T. Popa", Iaşi, Romania, Medical Semiology and Gastroenterology, Iaşi, Romania, ²"St. Spiridon" County Emergency Hospital, Institute of Gastroenterology and Hepatology, Iaşi, Romania, Gastroenterology, Iaşi, Romania

Contact E-Mail Address: simona.juncu@yahoo.com

Introduction: Spontaneous bacterial peritonitis (SBP) is a common bacterial infection in cirrhotic patients, which can lead to severe complication and even death. Proton pump inhibitors (PPIs), are associated with high susceptibility to enteric infections. The aim of this study is to assess if PPIs use in cirrhotic patients is a risk factor for developing SBP.

Aims & Methods: We conducted a retrospective study (January 2019 to March 2024) on all cirrhotic patients with ascites admitted in the Gastroenterology Department of "St. Spiridon" County Clinical Emergency Hospital Iaşi, a tertiary referral center. We identified all cases of SBP, defined as elevated ascitic fluid absolute PMN count > 250 cells/mm³, with or without positive ascitic fluid bacterial culture. We assessed previous PPI administration and their respective indications for all patients, to identify a potential risk correlation.

Results: Out of the 1530 cirrhotic patients, 832 (54,4%) were male and 698 (45,6%) were female, with a mean age of 54 years. One hundred and seventy-four patients (11.4%) were diagnosed with SBP. Among them, 50 patients (28.7%) presented previous treatment with PPIs, with a valid indication in 14 (28%) cases. Out of the 1356 cirrhotic patients with ascites but without SBP, 1098 (71.8%) patients had no history of PPIs use. Among the remaining 258 patients (16.9%) undergoing previous PPI treatment, 156 (60.5%) had a valid indication. PPIs were identified as a risk factor for SBP (OR 1.71 [95% CI 1.20 to 2.44]; P=0.0029).

Conclusion: Patients with cirrhosis and ascites who receive PPIs are at a significant risk of SBP, as previous studies have demonstrated. Moreover, given that most patients with SBP lacked a valid indication for PPIs, it is crucial to accurately assess their necessity for such treatment. These findings highlight once again the importance of a comprehensive clinical approach to managing cirrhotic patients.

Disclosure: Nothing to disclose.

EVALUATION OF NUTRITIONAL STATUS AND DIETARY INTAKE IN PATIENTS WITH LIVER CIRRHOSIS: A REAL-LIFE STUDY IN OUTPATIENTS AND HOSPITALIZED SUBJECTS

S. Khan¹, S. Sansoni¹, S. Di Cola¹, L. Lapenna¹, M. Merli¹
¹Sapienza University, Department of Translational and Precision Medicine, Rome, Italy

Contact E-Mail Address: saniya.khan@uniroma1.it

Introduction: Malnutrition and sarcopenia are two very frequent complications in patients with liver cirrhosis (LC). These conditions are associated with increased morbidity and mortality, particularly in advanced stages and require early investigation. Despite their significant impact on the prognosis, they are often overlooked and underdiagnosed.

Aims & Methods: Aim: To provide a general overview regarding the nutritional status and dietary intake in patients with LC and highlight any disparities in nutritional parameters between outpatients and hospitalized LC patients.

Methods: In this prospective observational study, all consecutive LC patients attending the portal hypertension clinic and those admitted to the gastroenterology ward at Policlinico Umberto I from May 2023 to January 2024 underwent nutritional screening. Demographic information, clinical characteristics, SARC-F questionnaire, anthropometric measurements, liver frailty index (LFI) parameters, 24-hour diet recall, and food frequency questionnaire were included in the screening. Data was analyzed using Student's t-test and chi-square test by Jamovi software version 2.3.28.

Results: Altogether 126 patients [male- 72.2%; age 63.7±10.7 years; etiology: Alcohol-53%, MASLD-19%, Viral-20%, Others-8%; MELD- 11.8±4.4; MELD Na- 13.6±5.5; 50% Child A] were enrolled. 36% of the patients were sarcopenic according to SARC-F questionnaire (score ≥ 4), with a mean LFI of 4.6±0.9. Although 65% of the patients consumed at least one protein source daily, only 15% achieved recommended daily protein intake, and 78% had lower energy intake than recommended. Of these 126 patients, 68.3% were outpatient and 31.7% were hospitalized, with comparable age and gender distribution. Hospitalized patients had a lower BMI (kg/m²) [24.7±4.1 vs 27.8±6.9; p=0.01], higher prevalence of frailty [5.1±1.1 vs 4.3±0.7; p=<0.001], lower TSF (mm) [12.4±6.8 vs 16.2±8.1; p=0.04], and lower MUAC (cm) [29.6±5.1 vs 32.2±5.6; p=0.02] than outpatients. Further, none of the hospitalized patients met adequate protein intake, contrasting with 22% of outpatients (p=0.01).

Variables	Outpatient (n=86)	Hospitalized patients (n=40)	p value
Age (years)	64.2 ± 9.8	62.6 ± 12.3	0.4
Gender (male)	68.6%	80%	0.1
BMI (kg/m²)	27.8 ± 6.9	24.7 ± 4.1	0.01
MELD	10.5 ± 3.4	14.7 ± 5.2	<.001
MELD-Na	11.9 ± 6.1	17 ± 4.4	<.001
CTP	A: 60% B: 39% C: 1%	A: 25% B: 50% C: 25%	<.001
Hand grip strength (kg)	22.3 ± 8.7	24.6 ± 9.1	0.4
Chair stands (sec)	14.4 ± 5.3	15.6 ± 4.6	0.4
LFI	4.3 ± 0.7	5.1 ± 1.1	<.001
Robust (≤ 3.2)	5%	0	
Pre-frail (3.3-4.4)	54%	38%	
Frail (≥ 4.5)	40%	62%	0.06

Table 1: Comparison between outpatient and hospitalized patients.

Conclusion: The impairment of nutritional status tend to increase in the more advanced stages of liver disease. There is a need for timely and routine assessment of nutritional status and implementation of targeted life-style interventions to optimize patient outcomes.

Disclosure: Nothing to disclose.

Contact E-Mail Address: drumairakbani@gmail.com

Introduction: Gallbladder microlithiasis (GBM), often undetected on conventional imaging, is accurately visualised by endoscopic ultrasonography (EUS). GBM is considered a potential cause of idiopathic acute pancreatitis (IAP). This study examines the incidence and outcomes of gallstone disease detected by EUS in patients with a GB in-situ and at least one prior episode of IAP.

Aims & Methods: The aim of this study was to assess the incidence and outcomes of gallstone disease detected by EUS in patients with IAP and intact gallbladders.

All IAP patients with an intact gallbladder referred for EUS between 2018-2020 were included and followed up for 3-6 years. EUS was conducted by 1 of 3 consultant gastroenterologists in a tertiary centre. Blood results and imaging findings were reviewed to identify predictive factors for GBM. Subsequent to EUS, outcomes including cholecystectomy and Endoscopic Retrograde Cholangiopancreatography (ERCP) were examined. Post-intervention incidence of gallstone-related complications and pancreatitis were recorded.

Results: 112 patients met the inclusion criteria (60 male and 52 female; median age 55 (IQR 21.8-70.1). 82/112 (73.2%) patients were diagnosed with definite GB and/or common bile duct (CBD) pathology at EUS. Diagnoses included GBM 67/82 (81.7%), GB stone 12/82 (14.6%) and CBD stone 3/82 (3.7%). Six patients were lost to follow and were excluded from further analysis.

104/112 patients had recorded blood results prior to EUS. 35/39 (89.7%) patients with transaminitis were subsequently found to have positive findings on EUS compared with 41/65 (63.1%) without transaminitis. (χ^2 8.81, $p < 0.01$). 55/112 (49.1%) patients had normal imaging prior to EUS. The most common finding was biliary dilatation (15/112, 13.4%) which was not associated with positive EUS findings (χ^2 1.26, $p = 0.26$).

Once diagnosed with stone related disease, 62/76 (81.5%) patients were referred for a surgical opinion. Of these, 52/62 (83.8%) underwent a cholecystectomy. Mean follow-up was 4.03 years (SD: 0.92). During this time 3/52 (5.7%) patients developed a further episode of AP and of the 20/76 patients managed non-surgically; 2/20 (10.0%) developed AP subsequently (χ^2 0.40, $p = 0.53$).

4/76 patients underwent ERCP (3 therapeutic, 1 prophylactic sphincterotomy); none developed further episodes of AP during the follow up period.

Conclusion: EUS is a useful diagnostic test in IAP patients. The most common EUS diagnosis in IAP is stone-related disease. A large proportion of patients diagnosed with GBM had a cholecystectomy, with a low incidence of AP and stone related complications during extensive follow up. A Pre-procedural transaminitis was associated with stone-related disease. Further prospective research is required to examine the benefits of cholecystectomy over conservative management.

Disclosure: Nothing to disclose.

Introduction: Several scores are available for the prognosis evaluation of acute pancreatitis (AP) at diagnosis. However, each has limitations. We trained an artificial intelligence-based model called EASY (early achievable severity index) to predict AP course. This study compares the prognostic values of the EASY score and the widely used bedside severity index (BISAP).

Aims & Methods: The EASY model was previously trained in 1184 cases and validated on a cohort of 3543 patients using data generally accessible on admission (medical history, anamnestic data, physical examination, laboratory parameters, imaging results). The EASY score increases with severity and ranges from 0 to 1. We further defined a categorical EASY score ([0, 0.2] -> 0, [0.21, 0.4] -> 1, [0.41, 0.6] -> 2, [0.61, 0.8] -> 3, [0.81, 1] -> 4). The evaluated outcomes were mortality, severity (based on Atlanta classification), and a binary EASY variable used during model training (=1 if the case is severe or lethal and otherwise 0). We calculated the area under the ROC curve (AUROC), sensitivity, precision and accuracy of each score for predicting the outcomes of interest.

Results: 1073 cases were included in the analysis. EASY and EASY categorical performed similarly and were superior to BISAP for mortality prediction (AUROC -EASY: 0.755 CI(0,676-0,829), EASY-categorical: 0.739 CI(0,658-0,811), BISAP: 0.708 CI(0,639-0,765)). The results were similar for severity (AUROC -EASY: 0.772 CI(0,73-0,813), EASY-categorical: 0.767 CI(0,721-0,802) BISAP: 0.72 CI(0,683-0,768)). However, the BISAP had slightly higher precision in predicting all outcomes. (Mortality -BISAP: 0.163 CI(0,085-0,256), EASY:0.151 CI(0,101-0,203); EASY-categorical: 0.203 CI(0,133-0,279); Severity: BISAP: 0.388 CI(0,27-0,505), EASY:0.313 CI(0,257-0,362), EASY-categorical:0.382 CI(0,322-0,474)).

Conclusion: The EASY score is overall superior to BISAP in predicting mortality and severity in AP. Being highly reliable and using data easily collectable on admission, the EASY-APP has great premises for becoming a reference tool for AP prognosis evaluation.

Disclosure: Nothing to disclose.

Introduction: Necrotic collections and especially infected necrotic collections, developing in 5-10 % of patients, drive mortality in severe acute pancreatitis. Minimally invasive drainage is indicated in infected necrotic collections. The mode of drainage depends on technical feasibility and local expertise and often percutaneous drainage is performed singly or in addition to endoscopic drainage. However, current guidelines do not provide specific recommendations on how to handle percutaneous drains.

Aims & Methods: This retrospective, multicenter analysis aims to investigate common practice of percutaneous drainage therapy of pancreatic necrotic collections (WOPN and ANC) in patients with acute pancreatitis. Our goal was to detect possible advantages of different flushing regimens in regard to the primary endpoint length of hospital stay. The secondary endpoint was in-hospital mortality. All patients hospitalized for necrotizing acute pancreatitis with at least one percutaneous drain from 01/2016 until 12/2022 were included. Length of hospital stay and survival times were compared using Restricted Mean Survival Time (RMST). Bias correction for confounding factors was performed (age, sex, etiology, severity, ICU stay, admission year, volume of study site, number of necroses, use of antibiotics, drainage number, maximal necrosis size, location, detection of microbiological content, lumen, drainage duration, and flushing).

Results: 612 patients (67 % males) in 29 centres from 15 countries in Europe and [MK1] America were included in the analysis. Alcohol and gallstones account for 64 % of pancreatitis cases, the vast majority of them being moderate (30 %) or severe (63 %) episodes according to RAC. 57 % of patients presented with one necrotic collection, the rest had two or more. 69 % of necrotic collections were flushed. The flushing regimen was 3x daily in about half of the cases. After bias correction for confounding factors, the length of hospitalization or mortality did not differ between the flushed and non-flushed group (RMST ratio 1.027; 95% CI: 0.979,1.078, p value 0.278 and RMST ratio 1.021; 95% CI: 0.996,1.047, p value 0.098 respectively) or between the externally drained and the externally plus internally drained group (RMST ratio 0.982; CI 95% CI: 0.923,1.045, p value 0.564 and RMST ratio 1.021; 95% CI: 0.996,1.047, p value 0.098 respectively). Flushing with saline compared to flushing with antiseptics/antibiotics was associated to a significantly shorter hospital stay (RMST ratio 0.876; 95% CI: 0.817,0.939, p value <0.01), yet no difference in mortality (RMST ratio of 0.999; 95% CI: 0.946,1.055, p value 0.972).

[MK1]ein Zentrum aus Kanada + ein Zentrum aus Bolivien

Conclusion: This large retrospective multicentre study comprising 612 patients reveals heterogenic therapeutic regimens in necrotizing pancreatitis. A specific irrigation regime or combination of internal and external drains was not associated with a shorter length of hospitalisation or lower in-hospital mortality. Flushing with antibiotics or antiseptics does not appear to provide an improvement over flushing with saline.

Disclosure: Nothing to disclose.

Introduction: Heavy alcohol consumption is one of the most common etiological factor in the development of acute pancreatitis (AP). We have previously shown that ethanol (EtOH) decreases the expression and activity of the cystic fibrosis transmembrane conductance regulator (CFTR) which plays a key role in alcohol-induced AP development. Orkambi (Ivacaftor and Lumacaftor) is available to correct the impaired CFTR function and expression in cystic fibrosis patients.

Aims & Methods: Our aim in this study was to investigate whether Orkambi is able to decrease the severity of experimental AP. Intact guinea pig pancreatic ducts (PDs) were treated with different concentrations of EtOH (30; 50; 100 mM) alone and in combination with Ivacaftor and/or Lumacaftor (1; 3; 5 and 10 μ M) for 3, 7, 9 and 12 hours and CFTR expression and activity were evaluated by immunostaining and patch clamp, respectively. Alcoholic AP was induced in Orkambi-treated guinea pigs and standard laboratory and histological parameters were measured.

Results: Ivacaftor (10 μ M) and Lumacaftor (10 μ M) alone or in combination dose-dependently restored the localization and activity of the EtOH-damaged CFTR channel, during 12 hours of treatment. Oral administration of Orkambi decreased the severity of EtOH-induced pancreatitis.

Conclusion: We showed for the first time that Ivacaftor and Lumacaftor are able to restore the CFTR defect caused by alcohol and decreases the severity of pancreatitis. These results indicate that Orkambi may represent a novel therapeutic option in the treatment of AP.

The research was funded by the National Research, Development and Innovation Office (SNN134497 to VV, K135874 to ZR and K131996 to PH) and the Translational Medicine Foundation.

Introduction: In the early phase of acute pancreatitis (AP), fluid resuscitation plays a crucial role. Changes in fluid distribution, increased capillary permeability, minimized intravascular volume, and loss of vascular resistance may lead to cardio-vascular and renal failure. On the other hand, overhydration is associated with cardiac decompensation and respiratory failure. Previously, intensive fluid therapy with large volumes of crystalloids was recommended without addressing individual needs for fluid therapy.

We used measurements of physiological parameters focusing on cardiac function and changes in body composition, to study the association between fluid therapy and physiological response, in the patient with AP.

Aims & Methods: This study aimed to assess fluid distribution in relation to fluid therapy, inflammation, and cardiac- and renal function in the early phase of AP.

This was a single-centre, prospective observational cohort study. On baseline, day 1, 2, 10 and 90 following were assessed: preload dependency (passive leg raise manoeuvre and defined as a >10% increase in stroke volume), hemodynamic parameters (stroke volume, cardiac output measured by non-invasive monitoring (Non-invasive LiDCOrapid™; LiDCO, London, UK)), bioimpedance variables (weight, extracellular water (ECW), total body water (TBW) by seca mBCA 525, Germany). White blood count (WBC), C-reactive protein (CRP), and creatinine were measured and Modified Marshall score was calculated on each time point. Data are presented as medians with interquartile range (IQR). [JK1] Pearson correlation coefficient was used to assess the relationship between changes in weight and haemodynamic and bioimpedance parameters.

Results: Eighty-eight patients with first-time AP were included. Median age was 58 years, 46 were females. Gallstones were the predominant etiology (55%). At baseline, 35 patients (40%) were preload dependent. However, the median increase in weight during the first 10 days of admission was 2.65 kg (IQR: 0.9;4.73). Across time points, patients in the fourth upper quartile of weight increase had significantly higher volume of ECW than patients in the 1-3. quartile ($p=0.02$). No differences were observed for stroke volume, nor cardiac output. CRP was significantly higher in patients in the fourth upper quartile of weight increase than in patients in quartile 1-3. No difference was found for WBC and creatinine.

We found a significant correlation between increasing bodyweight and extracellular water volume, $R=0.383$, ($p<0.0001$), but not between increasing bodyweight and stroke volume $R=-0.016$ ($p=0.783$) or cardiac output, $R=0.015$ ($p=0.796$). Also, a significant correlation was found between creatinine and increasing weight, $R=0.229$ ($p<0.0001$). Modified Marshall score was significantly correlated to increasing body weight, $R=0.159$ ($p=0.006$).

Conclusion: The assessment of hydration status in AP requires an in-depth knowledge of body fluid homeostasis. Our data provide physiological rationale for emerging evidence regarding more restrictive fluid resuscitation. Personalized- and goal directed therapy may be a promising novel way in the transition from necessary fluid resuscitation to harmful fluid volume accumulation in the early phase of AP.

Introduction: Acute pancreatitis (AP) is a potentially life-threatening disease that causes local and systemic inflammation with heterogeneity in terms of AP severity.

Aims & Methods: Prospective longitudinal study of total of consecutive patients diagnosed with first episode of AP. Excluded patients with previous pancreatic exocrine insufficiency (PEI) and follow-up <6 months until EPI diagnosis. The aim of this study is to determine if and when PEI occurs after AP and which inflammatory, nutritional and immunological factors determine its occurrence. The variables were the development of PEI (elastase fecal-1 levels <200µg/g) and pancreatic endocrine insufficiency (PENI) (diagnosed by fasting serum glucose, HbA1c and oral glucose tolerance test according to updated The American Diabetes Association criteria) over time and clinical, serum and fecal markers, imaging and outcome variables.

Results: A total of 78 patients were enrolled (69.2% (n=54) males; mean age: 62.4±2.0 yo), 75.6 with alcoholic/biliary etiology. AP was moderately-severe in 38.6% and severe in 15.4%. PEI was diagnosed in 43.6% (n=34; mean fecal elastase 1:149.2±167.4 vs. 435.6±100.3; p<0.001), being 73.5% at the time, 17.6% at 1 month, 14.7% at 3 months and 2.9% at 6 months of AP diagnosis. Thirteen (33%) PEI patients had mild AP. PENI was present in 27.1% (n=17) of patients and 19.2% (n=15) had previous diabetes mellitus. One patient died of pneumonia with respiratory failure acute pancreatitis-related before completing follow-up.

After univariate/multivariate analysis, the statistically significant predictive factors for PEI following AP were younger age (58.0±17.0 vs. 65.9±16.8; OR=0.028; p=0.017), severe AP (11.5 vs. 3.8%; OR=4.920; p=0.026), con-

comitant PENI (14.1% vs. 7.7%; OR=5.918; p=0.049), low sodium (135.6±5.4 vs. 138.2±2.8; OR=0.223; p=0.002), low potassium (3.9±0.4 vs. 4.2±0.63; OR=0.867; p=0.047), low osmolality (275.4±11.4 vs. 277.1±27.5; OR=0.004; p=0.029), high vitamin B12 (1196.8±1330.6 vs. 512.0±451.27; OR=0.001; p<0.001), high ferritin (924.3±847.8 vs. 465.5±360.9; OR=1.001; p=0.006), high triglycerides (707.9±105.5 vs. 105.5±43.1; OR=1.001; p=0.016), low magnesium (1.8±0.3 vs. 2.0±0.2; OR=0.174; p=0.022), high zinc (0.9±0.3 vs. 0.8±1.1; OR=1.055; p=0.021), high total lymphocytes (1699.8±663.2 vs. 1247.8±500.2; OR=1.001; p<0.001) and high CD3 lymphocytes (1248.4±558.6 vs. 886.3±467.3; OR=1.001; p=0.002).

Conclusion: PEI is frequent after AP, being >1/4 diagnosed up to 6 months follow-up and 1/3 in mild AP. Patients with severe AP, PENI (occurring in >1/4 of patients), low sodium, potassium, osmolality and magnesium, and high vitamin B12, ferritin, triglycerides, zinc, lymphocytes and CD3 lymphocytes have a higher risk of PEI. A closer follow-up of AP patients is crucial and should include severity, inflammatory, endocrinological, nutritional, and immunological assessment.

Introduction: Management of pancreatic fluid collection (PFC), a serious late complication of acute pancreatitis, is critical to the improvement of its prognosis. Technical innovations such as endoscopic ultrasound (EUS)-guided drainage, lumen-apposing metal stents (LAMSs), and endoscopic necrosectomy (EN) have facilitated the minimally invasive approach to symptomatic PFCs that previously required surgical interventions. Although there has been extensive research, there remains a lack of consensus on important aspects such as the optimal timing of interventions, stent selection, and indications for necrosectomy. A better understanding of the variations in the treatment strategies would help us to identify unmet needs in this setting and design clinical studies for the standardized treatment algorithm.

Aims & Methods: To clarify the current status of PFC management in Japan and address unresolved issues. A comprehensive questionnaire survey was e-mailed to 80 centers with pancreatobiliary interventional endoscopists in Japan. The questionnaire consisted of 40 questions about the criteria for treatment indications, stent selection, and direct endoscopic necrosectomy as well as 6 case vignettes.

Results: A total of 73 centers responded to the questionnaire (response rate, 91.3%). Regarding the timing of EUS-guided drainage, 48 centers (65.8%) initiated treatment when the encapsulation of a PFC was confirmed within 4 weeks of the onset of pancreatitis, while 18 centers (24.7%) did at the same timing even if the encapsulation was considered incomplete. It should be noted that despite the revision of the Atlanta Classification and the proposal to define encapsulation as pancreatic necrosis after 4 weeks, a significant number of centers chose to perform intervention before that time. For symptomatic walled-off necrosis (WON) with low-level liquification, 45 centers (61.6%) chose a LAMS, and 16 centers (21.9%) injected saline to facilitate the expansion of the proximal flange of LAMS. The criteria for LAMS placement varied, with 8 centers (11.0%) using a liquid component of 50% or more as a criterion. On the other hand, 6 centers (8.2%) tended to perform EN and place a LAMS de-

spite the prominent presence of necrotic material. Regarding the indications for necrosectomy, 44 centers (60.3%) chose it when there was no improvement after drainage, while 22 centers (30.1%) performed it during or immediately after the initial drainage session when necrotic material was prominent. Forty-nine centers (67.1%) performed necrosectomy between 2 and 7 days after endoscopic drainage. All centers confirmed the absence of pseudoaneurysms before drainage, with prophylactic transcatheter arterial embolization performed in 64 centers (87.7%).

Conclusion: This Japanese multicenter survey revealed considerable variations in treatment strategies for PFC in terms of the timing and indications of interventions and stent selection. The findings of this study emphasized the need for continuous data collection and analysis to fill current gaps in treatment approaches. Future research should aim to develop evidence-based guidelines that can clarify the optimal timing of treatment and intervention criteria.

Introduction: Acute pancreatitis (AP) is a systemic inflammatory disorder with rising incidence and high mortality in severe cases. Cardiac abnormalities, even heart failure, are commonly seen phenomena during and after AP-related hospitalization.

Aims & Methods: Our aim is to investigate the bidirectional association between cardiac changes and AP outcomes. The protocol was registered on PROSPERO (CRD42023479679, CRD42023479674). We conducted a systematic search on the 5th of November 2023 in three main databases (PubMed, Embase, CENTRAL) and selected the articles based on pre-defined selection criteria. We were searching for articles including patients with AP and cardiac abnormalities [e.g. atrial fibrillation (AF), echocardiographic changes] and looked at different clinical outcomes. Pooled odds ratios (pOR) with 95% confidence interval (CI) were calculated using a random-effects model.

Results: Nine eligible articles were included in our meta-analysis. By analyzing 1.3 million AP patients, those with AF have almost three-times higher odds for in-hospital death, than patients without AF (pOR: 2.89, CI: 1.26 - 6.66). Patients with severe AP have three-times higher odds for in-hospital QTc interval prolongation than patients in the non-severe category (pOR: 3.31, CI: 1.19 - 9.21).

Conclusion: Patients with AF face a threefold increased odds for death and those with severe AP are three times more likely to develop QTc in-

terval prolongation. Cardiology screening, including ECG, is crucial for AP patients. Longitudinal studies are needed to assess the long-term relationship between AP and cardiac abnormalities.

Introduction: With the obesity epidemic, the number of related health conditions have also markedly increased. As a result, the prevalence of metabolic syndrome (MS) reached 25% in western countries. In the severe form of acute pancreatitis (AP), mortality rate may be as high as 50%. Earlier studies associated the elements of MS with more complications, increased severity and mortality in AP. The aim of our meta-analysis was to identify the most important risk factors by investigating the individual and synergistic effect of MS factors on AP outcome.

Aims & Methods: Our systematic search was performed in three databases (MEDLINE, Embase and CENTRAL) from inception to 1 November 2023. Articles were selected according to predefined eligibility criteria. We investigated the effect of four MS factors: obesity, hypertension, diabetes mellitus and hypertriglyceridemia on AP outcome. We calculated pooled odds ratios (OR) with 95% confidence intervals (CIs). Risk of bias assessment was carried out with the Quality in Prognostic Studies (QUIPS) tool. The protocol was registered in PROSPERO under number CRD42023471092.

Results: We identified 15,904 unique records, and after the selection process, 103 studies were included in our analysis. Based on the results of four articles with a total sample size of 137,000, patients with MS are more likely to have moderately severe and severe, rather than mild AP (OR=1.687, CI:0.593-4.803). The odds of developing severe AP is almost 40% increased in the MS patient group (OR=1.398, CI:0.918-2.129). The risk of mortality is also increased in the group with MS (OR=1.307, CI:0.240-7.102). When analyzed individually, hypertension was a statistically significant predictor of both mortality (OR=2.564, CI:1.392-4.723) and disease severity (OR=1.792, CI:1.399-2.296) in AP.

Conclusion: MS and hypertension individually worsen the outcome of AP and may serve as a clinical predictor of severity and mortality.

Disclosure: Nothing to disclose.

Introduction: Acute pancreatitis is a multifactorial condition which despite showing a mild disease course in the majority of patients can be associated with significant morbidity and occasional fatality. Until lately, aggressive fluid expansion has been an undisputed aspect about managing the early stages of acute pancreatitis. Evidence produced by recent studies including the WATERFALL trial [1] supports a more conservative approach of fluid resuscitation given the fact that patients face significantly higher odds of relevant fluid overload while experiencing no benefit of their underlying condition. However, owing to strict inclusion criteria, results obtained from the WATERFALL trial only apply to patients with non-severe pancreatitis.

Aims & Methods: This retrospective monocentric study is thought to shed light on fluid-related complications in pancreatitis patients with any degree of severity. Altogether, n = 129 patients with all-cause acute pancreatitis including moderately severe and severe courses were enrolled and divided into 3 groups based on their cumulative fluid administration within the first 24 hrs (restrictive: < 3 L, moderate: 3 – 6 L, aggressive: > 6 L). Vital sign records and laboratory values were reported at defined time points (baseline, t = 48 hrs, t = 7 days). Fluid replacement was guided by institutional protocols with an initial bolus of 10 ml/kg, followed by a high-volume infusion rate of 4 ml/kg/h (< 24 hrs). Clinical response to fluid administration was monitored by changes in mean arterial pressure (> 65 mmHg), urine output (> 0,5 ml/kg/h), hematocrit (< 44 %), and blood urea nitrogen (< 25 mg/dl) at t = 12 and 24 hrs, respectively.

Results: The majority of patients were allocated to the group of moderate fluid resuscitation (n = 76, 58,9 %). At baseline, patients did not differ in systemic disease severity as indicated by SIRS and SOFA scores. Compared with a restrictive and moderate fluid regime, a significantly higher proportion of patients with moderately severe or severe pancreatitis associated with an acute peripancreatic fluid collection had previously been administered > 6 L fluids (> 6 L: 17/33, 52 % vs. < 3 L: 2/20, 10 % and 3 – 6 L: 24/76, 32 % vs., p = 0,001). Patients receiving > 6 L fluids were significantly more likely to show at least one radiological feature of pulmonary fluid overload (> 6 L: 15/33, 45 % vs. < 3 L: 2/10, 10 % and 3 – 6 L: 16/76, 21 %, p = 0,006), be transferred to intensive care unit (> 6 L: 18/33, 55 % vs. < 3 L: 2/20, 10 % and 3 – 6 L: 21/76, 28 %, p = 0,002), and require extended in-patient care (8, 6 – 11 days vs. 6, 4 – 7 days and 6, 4 – 10 days, p = 0,025). In addition, within 72 hrs after admission these patients had a significantly lower Horowitz ratio compared with restrictive and moderate group (> 6 L: 285, 239 – 337 vs. < 3 L: 360, 319 – 360 and 3 – 6 L: 337, 304 – 390, respectively, p = 0,003). At t = 48 hrs, C-reactive protein levels were significantly higher in patients with > 6 L (> 6 L: 164, 74 – 260 mg/l vs. < 3 L: 58, 4 – 162 mg/l and 3 – 6 L: 95, 13 – 183 mg/l) while serum albumin levels were significantly decreased (> 6 L: 30, 27 – 32 g/l vs. 3 6 L: 34, 31 – 36,5 g/l and 36, 33,5 – 41,5 g/l, p = 0,001).

Conclusion: Besides conferring a significantly higher risk of pulmonary edema, excessive fluid replacement is significantly associated with moderately severe or severe disease courses of acute pancreatitis, prolonged hospitalization, and need for intensive care. Although the retrospective design does not allow conclusions on causal relationships, results imply that excessive fluid resuscitation not only increases the risk of iatrogenic

fluid overload but may additionally aggravate pancreatic inflammation. Our data suggest that further investigation on the appropriate fluid management in patients with moderate and severe acute pancreatitis is required.

Introduction: Irritable bowel syndrome (IBS) is a highly prevalent and challenging condition with limited therapeutic options. Chitin-glucan (CG) is a novel dietary prebiotic considered as a safe food ingredient by EFSA. To provide an alternative approach to the management of IBS patients, we evaluated in preclinical studies the roles of CG on visceral analgesia, intestinal inflammation and barrier function and performed an open-label trial in IBS patients.

Aims & Methods: Analgesic effect of CG used at a human equivalent dose (HED) of 1.5-3 g/d was evaluated in rats and compared to negative-tap water and positive-phloroglucinol control groups. Mice with DSS-induced colitis were used to analyze the anti-inflammatory properties of CG. Molecular mechanisms underlying analgesic, anti-inflammatory, and intestinal barrier-strengthening functions of CG were evaluated in human intestinal HT-29 epithelial cells. CG molecular modeling was developed to study its interactions with microbial cell walls.

A multicenter open-label trial was conducted in 120 patients with IBS (Rome IV criteria) treated with CG 1.5 g/d and simethicone 0.75 mg/d for 4 weeks. The primary endpoint was the responder rate, defined as the number of patients whose abdominal pain score decreased by $\geq 30\%$ from baseline at week (W) 4. The analysis was performed using the per-protocol set. Cardinal symptoms, impact of global symptoms on daily life, change in stool consistency, and improvement in defecatory disorders were evaluated.

Results: CG in animals was well tolerated. CG at 3g/d HED significantly decreased visceral perception by 14% after 2 weeks ($p < 0.01$) and reduced inflammation by 50% promoting mucosal regeneration in DSS-induced colitis mice. CG at 1.5g/d HED reduced visceral pain perception by 20% after 5 weeks of treatment ($p < 0.01$). At 3g/d HED, this analgesic effect was superior to phloroglucinol with a faster onset of action and a 50% inhibition of pain perception ($p < 0.0001$). The molecular mechanisms contributing to these analgesic and anti-inflammatory effects of CG involved a significant induction of μ -opioid receptor (MOR), cannabinoid-2 (CB2) receptor, IL-10 and a significant decrease of pro-inflammatory cytokines IL-1b and IL-8 mRNA. CG also significantly up-regulated barrier-related genes like muc5AC, claudin-2 and ZO-2. CG molecular modelling revealed a new property of the molecule as a chelator of gram-negative lipopolysaccharide (LPS), gram-positive lipoteichoic acid (LTA) and phospholipomannan (PLM) in fungi.

Overall, 100 IBS patients were evaluated. At week 4, 67% were abdominal pain responders (score: 5.8 ± 2.4 vs. 2.9 ± 2.0 , $p < 0.0001$). Similar improvements were observed for bloating (8.0 ± 1.7 vs. 4.7 ± 2.9 , $p < 0.0001$); 60%

responders), abdominal distension (7.2 ± 2.1 vs. 4.4 ± 3.1 , $p < 0.0001$; 53% responders), and impact of global symptoms on daily life (7.1 ± 2.0 vs. 4.6 ± 2.9 , $p < 0.0001$; 54% responders). Stool consistency improved in most patients (90% and 57% for patients with liquid and hard stools, respectively). Overall, 42% of patients with defecatory disorders reported very much/considerable improvements by 2 weeks. No severe adverse event occurred, and tolerability was rated “good” or “very good” by 93%.

Conclusion: CG decreased visceral perception and intestinal inflammation. It also impacted master genes regulation and direct binding of microbial products. CG-simethicone was well tolerated and improved IBS symptoms in an uncontrolled trial. A placebo-controlled trial with longer follow-up is now ongoing to confirm the benefits of CG in IBS patients.

Introduction: Diet is an essential regulator of brain function, evidenced by longstanding associations between nutrient intake and neuronal function, synaptic plasticity, and neurotransmitter release. Recent studies have suggested that diet may impact mental health and cognition and even convey susceptibility to neurodegenerative disease. However, there is little related neuroimaging evidence to date.

Aims & Methods: Our aim was to delineate the association between diet, brain structure and function. We studied 518 healthy participants from the Cambridge Centre for Aging and Neuroscience (CAM-Can) repository (261 male and 257 female, mean age $53 \pm .79$ years). Participants were clustered via their self-reported dietary intakes using K-means clustering. Resting-state functional, white matter tractography, and grey matter volumetry networks conditional to dietary cluster were analysed using network-based statistics, controlling for participant age and sex as nuisance covariates. Relevant clinical data comprising BMI and Hospital Anxiety and Depression Score (HADS) were compared between diet clusters using Welch's t-test.

Results: Four distinct dietary intake patterns were identified: balanced, meat-predominant, vegetarian, and raw vegetable-predominant diets. Specific dietary types – balanced, meat-predominant and vegetarian – were associated with increased functional, grey matter or white matter connectivity between regions comprising the bilateral insula, frontomedial cortex (FMC) and bilateral anterior cingulate cortex (ACC) ($p < 0.04$). A balanced diet was associated with significantly increased functional, structural, and white matter connectivity between frontal brain regions, including the orbitofrontal cortex (OFC), superior frontal gyri (SFG), and FMC ($p = 0.04$) when compared to other diet clusters. A balanced diet was associated with a significantly reduced depression score (HADS-D) ($p = 0.03$), compared to a meat-predominant one. The meat-predominant diet cluster was correlated with increased structural connectivity at the bilateral ACC ($p = 0.03$) and significantly increased BMI ($p = 0.01$), when compared to vegetarian diets.

Conclusion: In the largest study of its kind, we reveal the structural and functional connectomic brain associations of diet. Notably, the set of brain regions implicated have broader established roles across interocep-

tion, emotion, memory, reward and addiction. Our findings imply a possible physiological correlate for diet-induced changes in behaviour, weight, mood, and cognition previously observed in the literature, and pave the way for future research.

Introduction: Tenofovir disoproxil fumarate (TDF) when compared to tenofovir alafenamide (TAF) leads to lower body weight and plasma lipid concentrations; the mechanisms of these effects are unknown. (1-3) TDF as opposed to TAF is processed into free tenofovir (TFV) within enterocytes when absorbed from proximal duodenum. (4) The effect of TFV in enterocytes is unknown, but in kidney proximal tubular cells it may cause mitochondrial damage. (5,6) We hypothesize that TDF may damage enterocytes leading to reduced absorption of nutrients from this anatomical site.

Aims & Methods: People living with HIV without known gastrointestinal diseases receiving stable TDF (n=12) or TAF (n=12) containing regimen underwent gastroscopy with biopsies from proximal and distal duodenum.

Biopsy samples were scanned with Leica GT450 scanner and measurements taken in Neagen's neaLink digital pathology solution. Serum intestinal fatty acid-binding protein (I-FABP) was measured as a circulating marker of enterocyte damage. Plasma/serum concentrations of nutrients absorbed from proximal duodenum were measured. COX/SDH histochemical staining and electron microscopy (EM) were conducted to evaluate mitochondria.

Results: All participants were male. TDF and TAF groups were matched for third antiretroviral agent (58% integrase strand transfer inhibitor, 42% non-nucleoside reverse transcriptase inhibitor) and age (mean (SD) TDF group 55 (12) and TAF group 57 (16) years). Five patients in TDF group (celiac disease, helicobacter gastritis and 3 cases of esophagitis) and 2 patients in TAF group (2 cases of esophagitis) had a pathological macroscopic or histologic finding ($p=0.178$). The patient with newly diagnosed celiac disease was excluded from the rest of the analyses. Villi were flatter (337 (59) vs. 397 (42) μm , $p=0.016$), crypts deeper (200 (46) vs. 176 (27) μm , $p=0.243$), and villus to crypt ratio lower (1.5 (0.42) vs. 2.5 (0.51), $p=0.009$) in TDF vs. TAF group. I-FABP concentration was significantly higher in TDF vs. TAF group (3.0 (1.07) vs. 1.8 (0.53) ng/ml, $p=0.003$). TDF group had numerically but not statistically lower concentrations of folate; vitamins A, B1, D and E. COX/SDH staining showed signs of mitochondrial damage in 10 participants in TDF and 11 in TAF group. EM-studies showed similar mitochondrial damage in both groups.

Conclusion: TDF group displayed signs of villous damage especially in proximal duodenum when compared to TAF group. This together with increased I-FABP suggest enterocyte damage and may contribute to the clinical effect of TDF on lowering body weight and plasma lipid concentrations when compared to TAF. Our data do not support mitochondrial toxicity as the culprit behind the mucosal damage, as COX/SDH histochemistry suggested mitochondrial dysfunction and EM showed similar signs of abnormalities in mitochondrial ultrastructure in both groups. Larger studies are needed to evaluate concentrations of nutrients absorbed from proximal duodenum among TDF users.

DECODING CODES EARLY – IS GENETICS THE MISSING LINK?

S. T. A¹, D. Janakiraman¹, N. Deivamani¹

¹*Institute Of Child Health/Madras Medical College, Paediatric Gastroenterology, Chennai, India*

Contact E-Mail Address: tasindhu1989@gmail.com

Introduction:

Congenital Diarrhea and Enteropathies (CODEs) pose significant challenge for diagnosis and management. Genetic sequencing for children with CODEs has important implication in early diagnosis.

Aims & Methods: Among children with chronic diarrhea those suspected to have CODEs clinically and endoscopically during the period of March 2023 to Feb 2024 were included.

Clinical profile, endoscopic, histological and genetic analysis were studied in all children with suspected CODEs.

Results: Total 15(n=15) cases were included. Overall male preponderance 80%(n=12) was noted. Age at onset ranged from 2days of life to 15months with mean age of 4months. Of them, 10(66%) children had watery diarrhea, 4(26%) children had bloody diarrhea and 1(6.6%) child had fatty diarrhea.

Endoscopic and histological yield in CODEs children were found in 40%(n=4) and 30%(n=3) respectively in children with watery diarrhea, and in all children with fatty or bloody diarrhea.

Out of 10 children with watery diarrhea two children had syndromic facies, woolly hair and café-u-lait spots were diagnosed as Syndromic Diarrhea-Trichohepatoenteric Syndrome (THES). 3 of them had protein losing enteropathy(PLE) with two among 3 showing normal endoscopy and biopsy, finally turned out to be *enterokinase deficiency*, while one child with endoscopically viewed whitish speckled mucosa with patchy vacuolated surface on histology had *DGAT 1 mutation*.

Two children with watery diarrhoea had microvillous atrophy (*MYO5B*) and one with severe watery diarrhea had *NEUROG3* mutation. Glucose galactose malabsorption (*GGM*), and Congenital Tufting Enteropathy (*CTE*) were seen in other two children. Among children with bloody diarrhea, two had proctocolitis on histology confirming Very Early Onset Inflammatory Bowel Disease(VEO-IBD) with genetic mutation showing *CARMIL 2* and *RIPK1* mutation. Two children with bloody diarrhoea suspected to have IBD had chronic colitis with thrombotic complications suggesting *CD55 deficiency* with Hyperactivation of complement, Angiopathic thrombosis, and PLE (CHAPLE syndrome). child with fatty diarrhoea with endoscopic findings suggestive of intestinal lymphangiectasia and histology of duodenal biopsy showing lipid droplets was clinically and genetically diagnosed Abetalipoproteinemia and started on fat free diet with MCT oil and vitamin A,D,E,K supplements.

Genomic analysis are the final stand of diagnosing CODEs due to the overlap of the clinical phenotypes and lack of appropriate biomarkers. Genetic Analysis had 100% yield when CODEs were suspected. Overall mortality rate was 26%(n=4) in 1year follow-up in our study group.

Conclusion: Single gene disorders are common among CODEs patients. Early Genetic testing helps in accurate diagnosis and initiating appropriate therapy as endoscopy and histology has poor yield.

Introduction:

Endoscopic Gastroplasty (EG) is an endoscopic therapy to treat obese patients focusing on gastric body remodeling. We considered three different techniques: Endoscopic Sleeve Gastroplasty (ESG), Endoluminal Vertical Gastroplasty (EVG), and distal Primary Obesity Surgery Endoluminal (POSE2).

Aims & Methods:

This was a single center, randomized controlled trial (ClinicalTrials.gov NCT04854317) of obese patients who underwent EG (through ESG or EVG or POSE2) or a low-calorie Mediterranean diet (1600 and 1400 Kcal/day). Outcomes included technical success rate, serious adverse event rate, and efficacy of the three EG procedures at inducing weight loss, improving obesity related comorbidities and quality of life (QoL), compared to diet.

Results: From July 2020 to May 2022, 240 obese (body mass index 37.5 ± 3.5 kg/m²) patients (mean age 46 ± 10 years; females 87.8%; obesity class II 58.3%; hepatic steatosis as the main comorbidity in 70%) underwent EG (through ESG, EVG or POSE2, with 60 patients for each procedure, 180 patients in total) or a low-calorie diet (60 patients). In the EG group the technical success rate was 100%. The serious adverse event rate was 1.1%. The follow-up visit was attended by 100/180 (55.6%), 48/180 (26.7%) and 19/180 (10.6%) patients at 6, 12 and 18 months, respectively. They experienced $16.1 \pm 6.1\%$, $13.7 \pm 9.0\%$ and $14.1 \pm 11.0\%$ total body weight loss (TBWL) and $39.7 \pm 15.4\%$, $35.3 \pm 23.4\%$ and $34.7 \pm 27.3\%$ excess weight loss (EWL) at 6, 12 and 18 months, respectively, with no significant difference among the three techniques in both parameters ($p > 0.62$ in TBWL% and $p > 0.94$ in EWL% ANOVA tests) at 18 months follow-up. Concerning the low-calorie diet group, 31/60 (52%), 13/60 (22%) and 4/60 (6%) patients attended their 6, 12 and 18 months follow-up; they experienced $1.1 \pm 4.7\%$ TBWL ($p < 0.001$ versus EG group) and $2.3 \pm 9.8\%$ EWL ($p < 0.001$ versus EG group) at 18 months. Ninety seven of one hundred (97.0%), 37/48 (77.1%) and 16/19 (84.2%) patients achieved at least 5% TBWL, while 86/100 (86.0%), 32/48 (66.6%) and 15/19 (78.9%) achieved at least 25% EWL in the EG group at 6, 12 and 18 months follow-up, compared to 4/31 (12.9%), 1/13 (7.6%) and 0/4 (0%), and 3/31 (9.7%), 1/13 (7.6%) and 0/4 (0%) in the diet group, at 6, 12 and 18 months. Fatty liver disease, hypertension, hyperlipidemia, diabetes, and obstructive sleep apnea improved after the EG procedure at 18 months, while no improvement was observed in the

diet group. Also, the QoL measured by EQ-5D test improved at 18-month follow-up ($p < 0.01$) in the EG group, while no significant improvement was detected in the diet group.

Conclusion: EG through ESG, EVG and D-POSE are technically feasible and safe, and appear to be effective for the treatment of obese patients, compared to diet, at a medium term follow-up.

Introduction: Obesity is a chronic and recurrent disease. In the past few years, Endoscopic sleeve gastroplasty (ESG) has emerged as a minimally invasive technique to fill the therapeutic gap between medical and surgical approaches to obesity. ESG consists of full-thickness suturing of the gastric body to restrict gastric volume and impair gastric motility.

Most of the published data on ESG are limited to 12-24 months¹⁻⁶. In this study, we aim to report long-term results of ESG to implement further the evidence of long-term effectiveness in each BMI class.

Aims & Methods: A post-hoc analysis was performed on a prospective database including patients with obesity (BMI ≥ 30 kg/m²) who underwent ESG between May 2017 and May 2021 at a single tertiary Center. Before ESG, all patients were evaluated and identified as eligible for the bariatric procedure by the local bariatric multidisciplinary team. Weight loss outcomes (%EWL, %TBWL) were evaluated during follow-up and stratified according to obesity class. We evaluated the percentage of patients achieving %EWL $>25\%$, the current threshold defining the efficacy of a primary bariatric endoscopic procedure⁷, as well as percentage of patients achieving %TBWL $>10\%$, the minimum threshold associated with obesity-related comorbidities improvement⁸. All patients were included in a multidisciplinary follow-up scheduled at 1, 3, 6, and then every 6 months, as per routine clinical practice.

Results: Between May 2017 and May 2021, 252 subjects (73% Female) underwent ESG with a median BMI of 37.2 (35.3 - 40.8) kg/m² at baseline and a median age of 45 (36-54) years. No severe procedure-related adverse events occurred. Of 252 subjects, 58 (23%) had obesity class I (BMI 30-34.9), 120 (48%) had obesity class II (BMI 35-39.9), and 74 (29%) had class III obesity (BMI ≥ 40). Follow-up rate was 90.5% (228/252) at 12 months, 60.3% (152/252) at 24 months, and 30.2% at 30-36 months. Overall, 58% (44/76) of patients showed an %EWL $>25\%$ at 30-36 months of follow-up,

respectively. Similarly, 71% (54/76) of subjects showed a %TBWL > 5% 30-36 months after ESG. Weight loss results according to BMI class are reported in Table 1.

	Overall	Class I Obesity	Class II Obesity	Class III Obesity
%EWL 12mo	46.6 (27.9-63.2)	49.7 (30.4-66.3)	50.8 (32.7-64.0)	45.2 (27.8-57.1)
%EWL 24mo	39.3 (17.6-58.4)	39.3 (18.1-58.6)	41.5 (14.4-60.8)	31.3 (17.5-49.3)
%EWL 30-36mo	36.4 (21.0-66.3)	31.3 (6.4-54.7)	31.4 (13.0-54.8)	31.4 (13.0-54.8)
%TBWL 12mo	15.6 (10.3-21.3)	12.5 (6.5-19.4)	16.3 (10.5-22.4)	16.2 (10.5-22.6)
%TBWL 24mo	12.8 (6.4-19.4)	15.9 (10.3-21.3)	13.8 (4.5-18.9)	15.1 (7.6-22.9)
%TBWL 30-36mo	13.3 (6.7-23.8)	11.1 (4.5-18.3)	10.7 (4.4-18.2)	10.7 (4.4-18.2)
% of patients with %EWL > 25% (30-36mo)	58% (44/76)	77% (10/13)	68% (20/32)	42% (13/31)
% of patients with %TBWL > 5% (30-36mo)	71% (54/76)	77% (10/13)	75% (24/32)	61% (19/31)

%EWL and %TBWL are reported as median (Q1-Q3)
 %EWL: percentage of excess weight loss; %TBWL: percentage of total body weight loss; mo: months.

Conclusion: Despite limited by the follow-up loss, a common issue in clinical practice for obesity cohorts, our experience confirms that ESG in the setting of a multidisciplinary approach is a safe and effective procedure for the treatment of obesity, associated with sustained weight loss in all obesity classes.

Introduction: There is a close relationship between the rise in obesity and the increase in consumption of sugar-sweetened beverages. According to a report by the World Health Organization (WHO), about 18% of children and adolescents worldwide are affected by overweight or obesity. Sweet

beverage consumption is particularly high in this age group. The WHO recommends reducing sugar intake to prevent and treat obesity. Reduction of sugar intake can be achieved through partial substitution with alternative sweeteners. Erythritol is a naturally occurring non-caloric bulk sweetener. Unlike sugar, erythritol does not affect plasma glucose and insulin concentrations yet stimulates the release of gastrointestinal satiation hormones.

Aims & Methods: This study aimed to evaluate the impact of daily erythritol versus sucrose intake over 5 weeks on parameters of glycemic control, food intake and gastrointestinal symptoms in healthy adolescents.

In this randomized, double-blind, parallel trial, 30 healthy, lean adolescents (15 per group: mean $\pm$ SD; age: 16.9 $\pm$ 1.5 years; BMI: 20.9 $\pm$ 1.8 kg/m²) were included. For a duration of 5 weeks, they received a daily total of 36 g of erythritol (divided into two portions of 18 g in 150 mL tap water; ERY), or 25 g of sucrose (divided into two portions of 12.5 g in 150 mL tap water; SUC). During the week before and the last week of intervention, food intake was assessed by food records. Before and after the intervention period, an oral glucose tolerance test was carried out and blood samples were collected at fixed time points to measure plasma glucose and insulin. Homeostatic Model Assessment of Insulin Resistance (HOMA-IR) and Homeostatic Model Assessment of Insulin Sensitivity (HOMA-%S) were calculated. The Gastrointestinal Symptom Rating Scale (GSRS) was applied to assess gastrointestinal symptoms at 3 timepoints (before, during week 3, and after the intervention).

Results: In the erythritol-group, parameters of glycemic control were not significantly different in response to the intervention. In the sucrose-group Cmax for blood glucose was not significantly different but Cmax for blood insulin (PRE_{SUC}: 91.67 $\pm$ 33.71 mIU/L vs. POST_{SUC}: 127.38 $\pm$ 68.24 mIU/L; p = 0.030) and HOMA-IR (PRE_{SUC}: 1.79 $\pm$ 0.74 vs. POST_{SUC}: 2.51 $\pm$ 0.74; p < 0.001) were significantly increased, while HOMA-%S (PRE_{SUC}: 70.5 $\pm$ 47.3 vs. POST_{SUC}: 43.2 $\pm$ 12.5; p = 0.016) was significantly reduced after the intervention period. In the erythritol-group, total sugar intake (PRE_{ERY}: 90.3 $\pm$ 34.0 g vs. POST_{ERY}: 71.0 $\pm$ 36.0 g; p = 0.034) and total carbohydrate intake (PRE_{ERY}: 256.8 $\pm$ 54.8 g vs. POST_{ERY}: 211.1 $\pm$ 71.0 g; p = 0.038) were significantly reduced after the intervention period, while total caloric intake (PRE_{ERY}: 2113.7 $\pm$ 495.4 kcal vs. POST_{ERY}: 1855.1 $\pm$ 495.7 kcal; p = 0.068) showed a trend of reduction. In the sucrose-group, total sugar intake (PRE_{SUC}: 75.4 $\pm$ 31.2 g vs. POST_{SUC}: 92.4 $\pm$ 24.7 g; p = 0.073) showed a trend of increase after the intervention period, while total carbohydrate and total caloric intakes were not significantly different. The total score of GSRS was not significantly different between the groups but increased significantly over time in both groups (p = 0.045).

Conclusion: Daily erythritol intake in healthy, lean adolescents over 5 weeks did not affect parameters of glycemic control but led to a significant reduction of total carbohydrate and total sugar intake. In contrast, the sucrose intervention resulted in a significant increase in maximum insulin concentration and HOMA-IR, along with a significant decrease in HOMA-%S.

Introduction: The extreme dynamism of the microbial ecosystem in the early years of life represents a crucial stage for undertaking targeted interventions to contribute to proper immune structuring and reduce susceptibility to chronic disorders. One of the main factors involved is maternal diet, which can influence the infant's gut microbiome through vertical transfer of maternal microbes to infants during vaginal delivery and breastfeeding. In this study, the association between maternal gut microbiota, maternal diet during pregnancy and lactation, and infant gut microbiota was analysed.

Aims & Methods: Healthy pregnant women in the 3rd trimester (baseline) were enrolled and nutritional counselling interventions were carried out. Stool samples and clinical data of mother and child were collected at baseline (T0), at birth (T1), and at 3 months (T2). A Food Diary and the MDSS (≥ 16) index assessed nutrient intake. Gut microbiota analysis on faecal samples from mothers and offspring was obtained by MiSeq 16rRNA Illumina. Statistical analysis will be performed using GraphPad Prism 9.0.

Results: 14 pregnant women with pre-gravid BMI 22.9 ± 3.2 kg/m² and pre-gravid TEE 2030 ± 137.3 Kcal/day were included. 75% of the infants were term-born vaginally and exclusively breastfed. Pregnant women had a dietary pattern not adhering to Mediterranean diet with an improvement following the nutritional intervention (MDSS T₀: 13 ± 2.5 ; T₁: 16 ± 0.7). At T₁, following nutritional counselling, the assessment of nutritional intakes showed an improving trend in energy intake of carbohydrates, lipids, and fiber, compared to dietary reference value. At baseline, maternal gut microbiota showed an important abundance of Proteobacteria phyla. At T₁, a positive trend in increasing abundances of Verrucomicrobiaceae, *Akkermansia* and *Fecalibacterium* was observed. Analysis of the infant gut microbiota at T1 and T2, showed increased α -diversity values over time, driven by the appearance of new bacterial species. A structural difference in microbial species, such as *E. coli*, *Bifidobacterium* and *Staphylococcus*, *Veillonella*, was observed between infants born via vaginal or caesarean delivery.

Conclusion: Preliminary data suggests that a nutritional counselling intervention in the 3rd trimester of pregnancy could be a potential protective factor that positively influences intestinal bacterial colonization in offspring.

Introduction: Preterm birth complications such as sepsis and necrotizing enterocolitis (NEC), are the leading cause of death among neonates. (1) Preterm birth is likely associated with dysbalanced microbial colonization and immature intestinal epithelium at birth, which impacts functionality, and barrier function of epithelia once microbial colonization occurs. Both structural and functional maturation of the intestinal epithelium are required for sufficient digestion and absorption of nutrients. (2) Breastmilk (BM) has been shown to significantly reduce the risk of developing NEC in preterms, in contrast to infant formula (IF). (3) We hypothesize that this is partly explained by the fact that BM contains a unique fat component, the milk fat globule membrane (MFGM), absent in IF. MFGM comprises a triple membrane of polar lipids, embedding bioactive components such as proteins, phospholipids and gangliosides. MFGM has shown to induce elevated epithelial cell differentiation and enhanced barrier integrity in an allergic mouse model and an early life rat model. (4, 5) However, the effects of MFGM on human intestinal maturation are unknown. We studied the effects of MFGM on human intestinal maturation using *in vitro* human neonatal small intestinal organoids.

Aims & Methods: Primary human neonatal organoids were derived from ileal tissue collected during neonatal surgeries (age 5 weeks - 4 months). Three-dimensional organoids were exposed continuously for 7 days to either 0.25wt% MFGM-enriched whey or 0.25wt% whey protein isolate (WPI; whey protein control not containing MFGM). Differences in growth and morphology were assessed by brightfield microscopy. Organoid growth was assessed by quantification through ImageJ analyses. Epithelial maturation was defined by longitudinal expression of brush border enzymes sucrase isomaltase (Sis), lactase (Lct) and intestinal alkaline phosphatase (ALPI), epithelial differentiation into secretory Paneth cells (Lysozyme; Lyz) and Goblet cells (Mucin-2; Muc2), and decreased stemness (Lgr5). Epithelial maturation was assessed by immunohistochemical (IHC) staining and qPCR.

Results: Neonatal organoids stimulated with MFGM displayed slower growth rate and decreased Lgr5 expression compared to WPI and medium control. This was accompanied with a 15-fold increase in gene expression of ALPI and 18-fold increase in Sis, two brush border enzymes associated with epithelial maturation. Expression of Muc2 was increased in MFGM stimulated conditions compared to medium control. Additionally, IHC stainings showed higher expression of Lyz in MFGM stimulated organoids compared to control and WPI. This suggest that MFGM stimulation enhances maturation by increasing expression of brush border enzymes and epithelial differentiation, while reducing stemness.

Conclusion: Our data suggest that MFGM enhances epithelial maturation by enhancing expression of brush border enzymes and cell differentiation in a human primary neonatal organoid model.

DOES SMALL BOWEL BACTERIAL OVERGROWTH (SIBO) HAS A ROLE IN UNEXPLAINED PERSISTENT HALITOSIS?

A. Yusuf¹, A. Ahmed^{1,2}, R. Ahmed¹

¹City Hospital, Gastroenterology, Hargeisa, Somalia, ²City Hospital, Hargeisa, Somalia

Contact E-Mail Address: abdyus12@gmail.com

Introduction: Halitosis is a relatively common condition with significant psychosocial impact on patients. The aetiology of halitosis is multifactorial and can be due to oro-dental, ENT, pulmonary or gastrointestinal conditions.

Aims & Methods: We wanted to test if SIBO can play a role in unexplained persistent halitosis. We prospectively collected data on all patients who were referred or self-presented to our GI specialist unit with halitosis over a two-year period. The inclusion criteria for the study were all patients should have had a negative dental and ENT check. We excluded all patients with chronic pulmonary and GI conditions, and those who have had any antibiotic therapy in the preceding four weeks. The patients were tested for SIBO using Bedfont-UK Gastrolyzer system with Lactulose 10 g as a substrate. A ≥ 20 ppm rise in hydrogen by 90 minutes was considered positive as per the North American Consensus on Breath Testing.

Results: From August 2021 to August 2023, a total of 53 patients (males 56.7%, females 43.3%, average 40.9 years) with persistent unexplained halitosis met the inclusion criteria for the study. A total of 21 patients (39.6%) had a positive test for SIBO (males 38.1%, females 61.9%, average age 44.2 years). All patients with a positive test result were treated with either oral Co-amoxiclav or a combination of oral Ciprofloxacin and Metronidazole for a 14-day period, and were followed up at three months (table 1).

	Type of antibiotic therapy	Patients with full response at 3 months	Number of patients with partial response at 3 months	No response at 3 months	Lost to follow up
Positive SIBO test (n = 21)	Cipro/Metro (n = 13, (61.9%))	8 (61.5%)	3 (23.1%)	1 (7.7%)	1 (7.7%)
	Co-amox (n = 8, (38.1%))	5 (62.5%)	2 (25.0%)	1 (12.5%)	0

Table 1: Treatment outcomes for patients with positive SIBO test.

Conclusion: SIBO might be an important factor in patients with unexplained persistent halitosis, and their symptoms seem to respond well to antibiotic therapy. It would be prudent to carry out further larger studies with longer follow up period in order to establish the role of SIBO in patients with unexplained persistent halitosis.

Introduction: Capsule endoscopy screening for pangastrointestinal tumours during a single procedure is expected. Here, we developed a handheld guiding device using a neodymium magnet through which a conventional colon capsule endoscope without an internal magnet can be manipulated.

Aims & Methods: We aimed to determine its effectiveness and safety. In a randomized controlled trial, 96 patients harboring superficial oesophageal carcinomas, gastric tumours, or colorectal polyps or tumours (CRTs) were enrolled; 47 and 49 patients were allocated to the S group using a nonmagnetic sham device and the M group using this magnetic device, respectively. The primary outcomes were the per-patient diagnostic yields for the representative tumours or polyps and the per-lesion yields. The secondary outcomes were the observation rate at each gastric site, adverse events, and acceptability using a subjectively categorized questionnaire survey.

Results: Although the per-patient sensitivity and specificity of the representative gastric tumours in the S and M groups were 95.2% and 100.0%, respectively ($P=.4773$); and 96.2% and 92.3%, respectively ($P>.9999$), the per-lesion sensitivity of gastric polyps was significantly greater in the M group ($P < 0.0001$), especially those localized in the upper and middle portions and <5 mm in size. There were significantly distinct observation rates of total gastric sites in the S and M groups (87% vs. 98%, $P < 0.0001$). In both groups, the per-patient sensitivity and specificity of CRTs ≥ 6 mm and ≥ 10 mm were 90.9% and 96.7%, respectively; 92.5% and 98.2%, respectively; and 77.8% and 71.4%, respectively, for superficial oesophageal carcinoma.

There were no adverse events associated with magnetic guidance. The proportions of patients who reported “not at all” and “almost none” or “quite easy” and “fairly easy” for embarrassment, abdominal pain, and fear were higher than 80% and who desired CE at the next examination were 62.5% (60/96) in total.

Conclusion: This study provides evidence supporting the effectiveness, safety, and acceptability of magnetically assisted CE for pangastrointestinal cancer screening.

Introduction: Distinguishing T1a and T1b oesophageal adenocarcinoma is imperative under current treatment paradigms. Piecemeal EMR is suggested to be acceptable for T1a oesophageal adenocarcinoma whereas en bloc R0 excision is required for in T1b disease, offering a potential cure and mitigate recurrence. Thus, we sought to ascertain whether internationally renowned expert Barrett's endoscopists were able to make this distinction based on optical evaluation.

Aims & Methods: A set of 60 endoscopic images of histologically confirmed high grade dysplasia (HGD), T1a and T1b disease (n=20 for each) were compiled from consecutive patients at a single institution. Each set contained four images, and were standardized to include an overview, a close-up in high-definition white light, a near-focus magnification image, and a narrow-band image. Experts were blind to histology and invited to predict it for each set of images – HGD vs T1a vs T1b.

Results: 19 experts from 8 countries (Australia, USA, Italy, Netherlands, Germany, Canada, Belgium, and Portugal) participated. The majority have been practicing for >20 years, with a median annual case volume for Barrett's EMR of 50 (IQR 18-75), and Barrett's ESD of 25 (IQR 10-45). Oesophageal adenocarcinoma (T1a/b) could be distinguished from HGD, with a pooled sensitivity of 89.1% (95% CI: 86.7-91.2). When predicting the T-stage for T1b adenocarcinoma cases, the pooled sensitivity was 43.8% (95% CI: 38.5-49.2). Fleiss' kappa was 0.421 (95% CI: 0.399-0.442, P<0.001).

Conclusion: Expert Barrett's endoscopists can reliably differentiate T1a/T1b oesophageal adenocarcinoma from HGD. Although there is fair-to-moderate agreement for T-staging, T1a disease cannot be reliably distinguished from T1b disease. This may have implications on clinical decision making and selection of endoscopic treatment methods.

Introduction: The safety of endoscopic submucosal dissection (ESD) in the context of resecting superficial tumors on Barrett's esophagus (BE) has been well assessed. However, there is limited knowledge regarding the oncological follow-up of BE and Barrett's esophagus after a combination of endoscopic resection and radiofrequency ablation.

Aims & Methods: A prospective, multicentric study involving 141 patients, enrolled between December 2016 and January 2019, and followed for three years. These patients underwent ESD for suspicious neoplasia lesions on BE, either alone or in combination with BE ablation.

The primary outcome measure was the R0 resection rate for adenocarcinoma and high-grade dysplasia (HGD). Secondary outcome measures included rates of en bloc resection rate, R0 resection rate for adenocarci-

noma or low-grade dysplasia, adverse event rate, overall and recurrence free survival at one and at three years, and the rate of complete remission of intestinal metaplasia at one year and three years.

Results: The R0 resection rate for carcinoma and HGD was 84,6% (110/130). R0 resection rate for invasive carcinoma was 80,8% (80/99). Seven early complications (< 48 hours) were observed, including 5 cases of bleeding and 2 cases of aspiration pneumonitis. No perforations occurred. Seventeen cases of esophageal strictures were reported. Recurrence was observed in 10 patients at 3 months, including 5 at the resection site, 5 at 12 months, and 3 at 36 months, totaling 18 recurrences over 3 years. 14 patients died during the follow-up, with 3 deaths attributed to esophageal carcinoma. The Complete Response to Intervention Monitoring (CRIM) was 63.7% in patients treated for Barrett's esophagus.

Conclusion: Endoscopic submucosal dissection is a safe and effective technique for treating early neoplastic lesions on BE, especially when combined with residual BE ablation. This study, one of the largest prospective studies on the subject, not only confirms the safety and efficacy of ESD but also provides valuable insights into post-resection tumor follow-up.

Introduction: Gastric cancer is the 5th most common cancer globally(1). Europe's Beating Cancer Plan recognises the urgent need for a gastric cancer screening strategy(2). One promising approach, outlined in the Maastricht VI/Florence consensus report, suggests integrating screening modalities for gastric cancer, such as gastroscopy with colorectal cancer screening (3). This method holds the potential for cost-saving benefits through combined screening efforts (4).

Aims & Methods: We aimed to determine the prevalence of preneoplastic and neoplastic lesions in a high-risk age group, in those who underwent gastroscopy at the time of colonoscopy. Our secondary aims were to determine a) the quality of endoscopy performed and b) the endoscopic burden for pathology that required follow-up.

This was a single-centre review and audit of key performance indicators in a colorectal cancer screening centre. The age group targeted was 50-74, i.e. the target group for colon cancer screening in Europe. We included those undergoing colonoscopy for polyp surveillance or as part of the national colon cancer screening programme. Participants with red flag symptoms (iron deficiency anaemia, weight loss, dysphagia), family history of gastric cancer, established diagnosis of Barrett's, intestinal metaplasia, dysplasia or who had a gastroscopy in the last 3 years were excluded. The sample size required for a 95% confidence interval with a presumed positivity rate of 5-7% was 101. Descriptive statistics, correlations and associations were examined using Stata software.

Results: 101 patients were included; the median age was 59;38% were male. Indications for gastroscopy included abdominal pain (45%), chronic reflux (37%), chronic dyspepsia (7%) and other (9%). All patients had

a technically complete gastroscopy (D2 intubation rate 100%, retroflexion 100%), the median procedure length was 7 minutes (range 4–21). 93% of patients had a macroscopic finding at the time of gastroscopy. Findings included gastritis (chronic superficial, chemical) (60%), hiatal hernia (50%), oesophagitis (28%), duodenitis (24%), gastric body polyps (10%), Barrett's mucosa (8%), benign gastric or duodenal ulceration (9%), Schatzki ring (4%), erosions (4%), intestinal metaplasia (IM) (1%), oesophageal candidiasis (1%) and varices (1%). 59% had biopsies taken from two topographical sites as per MAPS guidelines. On biopsy, *Helicobacter pylori* infection was found in 15% (15/101), 7% had intestinal metaplasia (IM); no atrophy, dysplasia or cancer was detected. In those with IM who had MAPS biopsies (5/7), all were focal IM. In those with suspected Barrett's (n=8), 88% had biopsies taken in accordance with the Seattle protocol and the Prague classification was used in 50% of cases. Additional pathology encountered included histological evidence of antral gastritis (56%), body gastritis (53%), reflux oesophagitis (21%), Barrett's without dysplasia (4%), duodenitis (3%), and eosinophilic oesophagitis (1%). There was no statistical difference in age ($p<0.82$) or gender ($p<0.32$) in those with pre-neoplastic changes on gastroscopy.

Conclusion: 11% of individuals within the target age bracket exhibited a pre-neoplastic condition on gastroscopy and/or histology (i.e. gastric intestinal metaplasia, gastric atrophy or Barrett's oesophagus), a further 15% were diagnosed and treated for *Helicobacter pylori* infection, the leading cause of gastric cancer. Among these cases, 4–7% necessitated subsequent surveillance gastroscopy. Our findings support the role of dual endoscopic screening with quality gastroscopy as a potential strategy for gastric cancer screening.

Introduction: The depth of early gastric cancer is an important factor in determining the treatment plan such as endoscopic resection or surgery. We developed an artificial intelligence (AI) program using deep neural networks to diagnose mucosal and submucosal cancers using endoscopic images. Performance evaluation tests were conducted for clinical applications.

Aims & Methods: A validation dataset was established comprising 204 patients with early gastric cancer who underwent endoscopic resection or surgery at our hospital during 2018–2021. The lesion sites were the upper part in 16 (8%), middle part in 106 (52%), and lower part in 82 (40%) patients. The median lesion size (range) was 14 (2–90) mm; the lesion depth was mucosal cancer in 136 (67%) and submucosal cancer in 68 (33%) patients. Five white-light images per case at a minimum were used (median: 8, range: 5–22). The primary endpoint was sensitivity of mucosal cancer, defined as the lower limit of the 95% confidence interval (CI) > 75%, based on previous reports on the depth diagnosis of early gastric cancer. The secondary endpoints were specificity and accuracy.

Results: Sensitivity of this program for the diagnosis of mucosal cancer was 91.2% (95% CI: 85.2%–94.9%), indicating the usefulness of this program. Specificity was 66.2% (95% CI: 54.3%–76.3%), and accuracy was 82.8% (95% CI: 77.1%–87.4%).

Conclusion: The AI program developed for diagnosing the depth of early gastric cancer is useful and expected to be applied clinically in the near future.

Disclosure: Nothing to disclose.

UTILITY OF A FOLLOW-UP ENDOSCOPY AFTER A DIAGNOSIS OF OESOPHAGEAL ULCER AND PREDICTORS OF MALIGNANCY AND DYSPLASIA

R. Osborne¹, M. Elphick¹, T. Archer¹, C.W. Sin^{1,2}, C. Winters^{1,2}, N. Mohammed^{1,2}, B. Rembacken¹, R. Sood^{1,2}, V. Goodoory^{1,2}

Introduction: Oesophageal ulceration (OU) is a frequent finding at oesophago-gastro-duodenoscopy (OGD). Despite limited data on the benefit of a repeat endoscopy, current guidelines recommend a follow-up OGD after six weeks to exclude underlying malignancy¹.

Aims & Methods: Aims: We aimed to explore the utility of a follow-up endoscopy after a diagnosis of oesophageal ulcer and identify predictors of oesophageal malignancy and dysplasia. Secondary aims were to estimate the environmental and financial impact of a follow-up endoscopy.

Methods: We collected demographic, endoscopy, and histology data from patients diagnosed with OU over a 5-year period (from 1st January 2016 to

31st December 2020 inclusive) at Leeds Teaching Hospitals NHS Trust. We collected data from the index OGD, follow-up OGD, and from their medical records up to 3 years after a diagnosis of OU at their index OGD. We examined the proportion of patients who were diagnosed with dysplasia or malignancy at follow-up or up to 3 years after their index OGD. Binary logistic regression was performed to identify predictors of oesophageal malignancy or dysplasia at index OGD, follow-up OGD, or 3 years after the index OGD. NHS national cost data for OGD, and carbon dioxide (CO₂) emissions were estimated for all unnecessary follow-up OGDs^{2,3}.

Results: In total, 409 patients were diagnosed with OU. Of these, 33 patients were diagnosed with oesophageal cancer or dysplasia, with 30 diagnoses (90.9%) made at the index OGD and the remaining 3 (9.1%) at either the follow-up OGD or within 3 years of the index OGD. Of those 3 patients, one was diagnosed with oesophageal carcinoma, one with low grade dysplasia, and one with high grade dysplasia, all within a segment of Barrett's oesophagus already diagnosed at the index OGD. Those who were diagnosed with oesophageal malignancy or dysplasia, compared to those who were not, were more likely to have larger ulcers (mean size (SD), mm, 15.9 (17.2) vs 9.50 (11.1), $P = 0.003$), endoscopic features suspicious for malignancy (69.7% vs 8.0%, $P < 0.001$), Barrett's oesophagus (54.5% vs 14.4%, $P < 0.001$), and biopsies taken at index OGD (100% vs 64.1%, $P < 0.001$), and less likely to have a proton pump inhibitor prescribed (57.6% vs 86.4%, $P < 0.001$) after the index OGD. Following logistic regression controlling for all data, those with endoscopic features suspicious for malignancy (OR = 45.9; 95% CI 10.3 to 204) and those with Barrett's oesophagus at index OGD (OR = 5.29; 95% CI 1.56 to 18.0) were more likely to be diagnosed with oesophageal cancer or dysplasia up to 3 years after the index OGD. A total of 376 unnecessary OGDs were undertaken over a 5-year period, the costs of which were estimated at £140,248 and 10.6 tonnes of CO₂ emissions.

Conclusion: Repeat OGD to exclude underlying malignancy following a diagnosis of oesophageal ulcer may only be required in those with endoscopic features suspicious for malignancy and those with Barrett's oesophagus. Larger prospective multi-centre studies, with cost and carbon footprint analyses, are required to confirm our results and to inform guidelines.

Introduction: Oesophageal squamous cell carcinoma (OSCC) necessitates additional therapy such as surgical resection or chemoradiotherapy following non-curative endoscopic resections, considered the gold standard treatment. However, in elderly patients, decisions regarding additional therapy tend to be conservative due to concerns about increased invasiveness and its impact on prognosis.

Aims & Methods: The aim of this study was to investigate the long-term outcomes in elderly patients (aged 75 and above) with OSCC diagnosed pathologically as non-curative following endoscopic resections. A retrospective analysis was conducted on OSCC patients treated with endoscopic resection, evaluating pathology findings and prognosis based on medical records. Non-curative resection was defined as pathology revealing SCC invading the muscularis mucosa (MM) or submucosa (SM). Exclusion criteria included patients with other active malignancy, those with less than 12 months of follow-up, and those pathologically classified as having positive vertical margins (VM1) or margins difficult to evaluate (VMX). T1a-MM OSCC with lymphovascular invasion (LVI) or T1b-SM OSCC often requiring additional therapy were considered as index lesions.

Results: Twenty patients were excluded from the study (other active malignancy: n=16, dropout: n=3, VM1/VMX: n=1). A total of 120 cases were analyzed, with 27 elderly patients and 93 non-elderly patients. The proportion of SM lesions was higher in elderly patients compared to non-elderly patients (44.4% vs. 20.4%, $p < 0.05$). Additional therapy was administered exclusively to the index lesions. There was no significant difference in the rate of additional therapy for index lesions between elderly and non-elderly patients (76.2% [16/21] vs. 63.5% [33/52], $p = 0.295$), although non-elderly patients were more likely to undergo surgery (30.8% [16/52] vs. 3.7% [1/27], $p < 0.01$). The median follow-up periods for elderly and non-elderly patients were 72.6 vs. 78.4 months, respectively, with no significant difference ($p = 0.11$). During follow-up, no metastatic recurrences were observed in elderly patients, with 3 deaths unrelated to OSCC. In non-elderly patients, metastatic recurrences were observed in 8 cases. Among patients with T1a-MM without LVI who did not receive additional therapy (41 cases), 3 experienced metastatic recurrence, and 2 deaths were attributed to OSCC. Two cases (10.5% [2/19]) with additional therapy for T1a-MM and 3 cases (21.4% [3/14]) with T1b-SM had recurrence. Among those who experienced recurrence, 60% (3/5) succumbed to OSCC. In non-elderly patients, 16 deaths occurred, with 6 attributed to OSCC. The 5-year overall survival rates for elderly and non-elderly patients were 100% and 86.1%, respectively ($p = 0.81$), with 5-year disease-specific survival rates of 100% and 93.5%, respectively ($p = 0.19$). The 5-year disease-specific survival rates for elderly and non-elderly patients with index lesions followed by additional therapy were 100% and 90.4%, respectively, with no significant differences ($p = 0.213$).

Conclusion: The long-term outcomes of elderly patients who underwent additional therapy after endoscopic resection for OSCC were comparable to those of non-elderly patients.

Introduction: Malignant gastric outlet obstruction (GOO) can arise from a spectrum of malignancies, including gastroduodenal, pancreaticobiliary, colorectal, breast, and lung cancers. Typically, GOO heralds a grim prognosis and manifests with symptoms such as nausea, bloating, vomiting, and abdominal pain. Presently, laparoscopic gastroenterostomy (L-GE) stands as the preferred therapeutic modality; however, endoscopic ultrasound-guided gastroenterostomy (EUS-GE) employing lumen apposing metal stents has emerged as a promising minimally invasive alternative. Comparative studies directly assessing the efficacy of EUS-GE versus L-GE remain scarce.

Aims & Methods: We aimed to compare EUS-GE with L-GE for the treatment of GOO using a propensity score-matched analysis.

In a retrospective, multicenter analysis, consecutive patients were enrolled between April 2019 and April 2024 from two academic centers and one primary care facility. To mitigate selection bias, propensity score matching was employed, taking into account factors such as underlying malignancy, tumor stage, and clinical performance status. Clinical success, defined as a reduction of gastric outlet obstruction (GOO) symptom scores by ≥ 1 , served as the primary outcome measure. Secondary endpoints included technical success, time to oral intake, occurrence of adverse events (AEs), length of hospital stay, and 30-day mortality.

Results: A total of 94 patients underwent EUS-GE, while 78 patients underwent L-GE, as per initial screening. Propensity score matching resulted in 72 patients allocated to each group in a 1:1 ratio. The mean age of the study cohort was 68.2 ± 12.3 years, with 59.7% being female. Clinical success rates were 90.2% for EUS-GE and 82.2% for L-GE ($p=0.25$). Technical success rates were 95.2% for EUS-GE and 100% for L-GE ($p=0.06$). The mean duration of hospital stay was significantly shorter for EUS-GE compared to L-GE (10.1 ± 13.4 days vs. 15.5 ± 10.5 days; $p<0.001$). Less AE were observed in the EUS-GE group compared to the L-GE group, both in total (4.8% vs. 22%; $p=0.01$) and in serious AE (1.6% vs. 6.7%; $p=0.3$). The 30-day mortality rate was 11.3% in the EUS-GE group and 17.8% in the L-GE group.

Conclusion: In patients presenting with malignant GOO, EUS-GE showed a tendency towards enhanced clinical success, although not statistically significant, while maintaining comparable technical success rates to L-GE. Notably, clinical recovery post-intervention and hospital stay duration were notably shorter in the EUS-GE cohort, accompanied by a significantly lower incidence of adverse events. Consequently, EUS-GE stands poised to emerge as a preferred therapeutic option for GOO. Nevertheless, further prospective, randomized trials are imperative to validate these retrospective findings.

Introduction: Post endoscopy upper gastrointestinal cancers (PEUGIC) can be missed opportunities to diagnose upper GI cancer earlier or even prevent cancer. Up to 71% are potentially avoidable but identifying and investigating PEUGIC is challenging. A process for identifying PEUGIC and performing root cause analysis was piloted and the results are described.

Aims & Methods: The aims of the project were to develop a system to identify all PEUGIC in the English NHS and to allow endoscopy providers to conduct standardised root causes analysis of their PEUGIC via an online platform. This study allows local learning from PEUGIC and quantifies the reasons why PEUGIC occur at a national level.

PEUGIC occurring 3-36 months after a non-diagnostic (index) endoscopy between 2017 and 2023 were identified from the final or provisional registration in National Cancer Registration and Hospital Episode Statistics Datasets held by the National Cancer Registration and Analysis Service. Data for root cause analysis were uploaded onto a secure root cause analysis portal following local hospital review. PEUGIC following surveillance or therapeutic endoscopies were excluded.

Results: 305 PEUGIC were examined by local reviewers in 13 hospitals in England. 40 were excluded, mainly due to errors in provisional cancer data. Data were available for 220 PEUGIC (83%). 136 (62%) PEUGIC followed diagnostic, follow-up or screening endoscopies. PEUGIC sites were oesophagus 63% and stomach 37%.

Table 1 shows the PEUGIC root cause analysis based on the World Endoscopy Organisation categorisation and Kamran Endoscopy 2022. A lesion detected but inadequate assessment or decision making occurred in 15% and a possible missed lesion with inadequate endoscopy or decision making in 17%.

Diagnoses on index endoscopy in oesophageal PEUGIC: pre-malignant lesion 21% (e.g. Barrett's), no abnormal finding 51%, focal lesion 22% and

cancer associated lesion 6% (e.g. ulcer). Findings on index endoscopy in gastric PEUGIC: no abnormal finding 38%, cancer associated lesion 30%, focal lesion 22% and pre-malignant lesion 10% (e.g. gastric atrophy). Gastric PEUGIC tended to present more with advanced cancer (41% stage 4 vs 33% oesophageal PEUGIC). 13% of oesophageal and 12% of gastric PEUGIC were considered potentially avoidable by reviewers. Treatment appeared adversely affected in 45% of oesophageal and 38% of gastric PEUGIC. Reviewer considered that 9% of PEUGIC led to premature death.

PEUGIC categorisation	Number of cases
1. Lesion detected, adequate assessment and decision making but PEUGIC occurred	45 (33%)
2. Lesion detected, inadequate assessment and decision making	20 (15%)
3. Possible missed lesion, endoscopy and decision making adequate	48 (35%)
4. Possible missed lesion, endoscopy or decision making inadequate	23 (17%)

Table 1 Root causes of PEUGIC examined.

Conclusion: Abnormalities in the area of the later cancer were detected in 45% of oesophageal PEUGIC and 52% of gastric PEUGIC. Inadequate lesion assessment, endoscopy and/or decision making was noted in 32% of PEUGIC. Many patients had incurable disease when later diagnosed and treatment appeared adversely affected in 42%.

Introduction: Janus Kinase (JAK) inhibitors are licensed for the treatment of ulcerative colitis with the benefits of a fast onset of action and a short half-life.[i] This makes them a potential treatment option for patients hospitalised with UC, including those previously treated with, or unsuitable for, infliximab or cyclosporine. There is currently limited published evidence in this setting, drawn from small case series.

Aims & Methods: We performed a retrospective analysis of data collected at 14 sites in the United Kingdom, including both tertiary IBD centres (n=10) and general hospitals (n=4) between January 2019 to January 2024. We included patients who were hospitalised due to active UC and commenced a JAK inhibitor for that indication during the same admission. Baseline data included disease duration and extent, prior exposure to advanced therapies, clinical and endoscopic assessments of disease activity and laboratory parameters. We reviewed treatments administered during the same admission, including corticosteroids and advanced therapies. Coprimary endpoints were colectomy rate at 30 days and 12 months. 12 week, 6 month and 12month persistence data was collected. Adverse outcomes and treatment persistence at the same time points were also recorded.

Results: 80 patients (filgotinib (n=15), tofacitinib (n=25) and Upadacitinib (n=40) were included, with a minimum of 12 weeks follow-up. 43/80 (54%) were male, mean age was 37±14, mean admission albumin 35 and CRP 52. Extent of disease was E1 1/80 (1%), E2 31/80 (39%) and E3 48/80 (60%).

63/80 (79%) of patients had prior anti-TNF exposure (infliximab 47/80 (59%), including 13/80 (16%) of whom had received it as a previous rescue therapy). 31/80 (39%) were on prednisolone at admission. 50/80 (63%) had a baseline endoscopic assessment within 72 hours of admission, of which 34/50 (68%) had severe (Mayo 3) endoscopic activity. During admission, prior to JAK inhibitor administration, treatments given included IV hydrocortisone (93%), methylprednisolone (5%), infliximab (4%) and cyclosporine (1%).

Colectomy rates were 8% and 14% at day 30 and week 12 respectively. In patients for whom 12-month follow-up data were available, 5/34 (15%) had undergone a colectomy at that timepoint.

There was one recorded herpes zoster infection and no recorded thromboses or major adverse cardiovascular events.

JAK Inhibitor	Started during admission (%)	12 week persistence (%)	6 month persistence (%)	12 month persistence (%)
Filgotinib	15/80 (19)	13/15 (87)	9/14 (64)	7/10 (70)
Tofacitinib	25/80 (31)	18/25 (72)	9/25 (36)	8/23 (35)
Upadacitinib	40/80 (50)	32/40 (80)	14/21 (66)	0/1 (0)

Table 1. JAK Inhibitor & Treatment Persistence.

Conclusion: JAK inhibitors appear to offer a valuable treatment option for patients hospitalised with active UC. This appears to be the case even in patients with prior anti-TNF exposure. 86% of patients avoided colectomy at 12 weeks, with a similar proportion colectomy-free at 12-months. The risk of adverse events was small. Our study is, to our knowledge, the largest dataset examining the initiation of JAK inhibitors for those hospitalised with UC.

Introduction: Many patients (pts) with moderately to severely active ulcerative colitis (UC) treated with biologics fail to respond or lose response and require alternative therapy.^{1,2} Upadacitinib (UPA), an oral reversible JAK inhibitor approved for treatment of adults with moderately to severely active UC, has shown efficacy in pts with an inadequate response, loss of response or intolerance to ≥ 1 biologic (biologic failure) or anti-TNF agent.³⁻⁵ However, data on the efficacy of UPA by the number and type of prior biologic therapies are limited.

Aims & Methods: This post hoc analysis evaluated clinical, endoscopic and safety outcomes of UPA in pts with UC with biologic failure by the number and type of prior biologics. After 8 weeks' (wks') induction therapy in the Phase 3 U-ACHIEVE or U-ACCOMPLISH trials, pts with clinical response to UPA 45 mg once daily (QD) were randomised to placebo (PBO), UPA 15 mg QD (UPA15) or UPA 30 mg QD (UPA30) for 52 wks in U-ACHIEVE Maintenance. In this study, efficacy was analysed by number (0 prior biologics failed [Non-Bio-IR], 1 or ≥ 2) of prior biologics. Outcomes were assessed after 8 wks' induction (pooled) and 52 wks' maintenance. Results are presented using non-responder imputation incorporating multiple imputation to handle missing data.

Results: Baseline pt (induction [n=988]; maintenance [n=681]) characteristics were similar across treatment arms in each subgroup by number of prior biologics, except pts who failed ≥ 2 prior biologics who had longer disease duration. Clinical and endoscopic outcomes were achieved by more pts who received UPA vs PBO after induction and maintenance, and by more pts who received UPA30 vs UPA15 in the ≥ 2 prior biologics group after maintenance. Furthermore, more pts who received UPA30 vs UPA15 and failed ≥ 2 prior biologics maintained clinical remission from Wk 0 of maintenance to Wk 52 (Table).

Adverse events (AEs) occurred at numerically higher rates for pts receiving UPA who failed ≥ 2 biologics in induction and maintenance studies. During induction, no malignancies or major adverse cardiovascular events (MACE) were reported, and there was 1 venous thromboembolic event (VTE) in the PBO group. During maintenance, across subgroups, rates of AEs of special interest were: malignancies (Non-Bio-IR: UPA15, 1.0 events/100 PY [E/100 PY]; UPA30, 1.8 E/100 PY; 1 prior biologic: PBO, 3.3 E/100 PY; UPA30, 5.5 E/100 PY; ≥ 2 prior biologics: UPA30, 1.8 E/100 PY), MACE (Non-Bio-IR: UPA30, 0.9 E/100 PY; 1 prior biologic: PBO, 3.3 E/100 PY) and VTE (Non-Bio-IR: UPA30, 1.8 E/100 PY), respectively. No AEs leading to death occurred in either study.

Efficacy endpoints n, (%)	Induction (8 weeks)						Maintenance (52 weeks)

^aAdapted Mayo score ≤ 2 , with stool frequency subscore ≤ 1 and not greater than baseline. RBS=0 and ES ≤ 1 without friability.

^bThe overall clinical response rate at Week 8 or Week 16 of UPA 45 mg QD induction therapy was 81.8%.

^cA decrease in Adapted Mayo score ≥ 2 points and $\geq 30\%$ from baseline, and a decrease in RBS ≥ 1 point or an absolute RBS of ≤ 1 .

^dES ≤ 1 without friability.

ES=0.

ES ≤ 1 without friability and Geboes Score ≤ 3.1 .

^eFor Non-Bio-IR, n=49, 43 and 53 for PBO, UPA 15 mg QD and UPA 30 mg QD, respectively. For 1 prior biologic: n=20, 17 and 13 for PBO, UPA 15 mg QD and UPA 30 mg QD, respectively. For ≥ 2 prior biologics: n=16, 16 and 21 for PBO, UPA 15 mg QD and UPA 30 mg QD, respectively.

^fClinical Remission per Adapted Mayo score at Week 52 among patients who achieved clinical remission at the end of induction therapy.

^gClinical remission per Adapted Mayo score at Week 52 and corticosteroid free for ≥ 90 days before Week 52 among patients who achieved clinical remission at the end of induction therapy.

ES, endoscopic subscore; HEMI, histologic endoscopic mucosal improvement; Non-Bio-IR, 0 prior biologics failed; PBO, placebo; QD, once daily; RBS, rectal bleeding subscore; UPA, upadacitinib.

Table. Efficacy after 8 weeks' induction and 52 weeks' maintenance therapy.

Conclusion: Clinical and endoscopic improvements were seen with UPA vs PBO in induction and maintenance therapy in pts with moderately to severely active UC, regardless of the number of prior biologics failed.

During maintenance, numerically greater treatment benefits were seen with UPA30 vs UPA15 in the ≥ 2 prior biologics group. AEs occurred at numerically higher rates in pts who failed more biologics.

Introduction: In the recent years, the therapeutic options for inflammatory bowel disease (IBD) have expanded. Multiple Janus kinase (JAK) inhibitors have been licensed: First Tofacitinib (TOFA) for Ulcerative Colitis (UC), followed, most recently, by Filgotinib (FIL) in UC and Upadacitinib (UPA) in UC and Crohn's Disease (CD).

Aims & Methods: The aim of the study was to explore the real-world effectiveness and safety of UPA in a multicenter Belgium refractory cohort of patients with moderate-to-severe CD.

This is an observational, national, retrospective multicenter study including all patients with active CD initiating UPA between September 2022 and January 2024 from 16 Belgian centers. Clinical remission and response were defined using the two-component patient reported outcome. Endoscopic response was defined as a decrease in baseline Simple Endoscopic Score (SES-CD) with $\geq 50\%$. Endoscopic remission was defined as SES-CD ≤ 4 or disappearance of baseline ulcers. Effectiveness endpoints were evaluated at week 12, 24 and 52, while CD-related hospitalization, surgery and safety were assessed throughout follow-up.

Results: Of the 66 patients who started UPA, 52 patients were analysed (6 excluded for ostomy and 8 for not having yet reached 24 weeks of follow-up) with a median follow-up of 21 weeks (IQR: 4-24). Patients were predominately female (54%), median age at baseline was 37 years old (IQR: 19-62) and median disease duration was 13 years (IQR: 0-29). 12% of the patients had ileal CD, 12% colonic CD, 76% ileocolonic CD with 17% concomitant upper gastrointestinal CD and 42% concomitant perianal disease. The majority of the patients (87%) was exposed to ≥ 3 biologics and 54% had previously undergone a CD-related surgery.

At week 24, 58% and 44% of overall eligible patients achieved steroid-free clinical response and remission, respectively. Endoscopic data were available in 17 out of the 52 patients of whom 65% and 47% reached endoscopic response and remission respectively within the first 24 weeks. Sixteen out of eighteen patients that used concomitant steroids at baseline were able to stop it by week 24.

Overall, 21 patients (40%) discontinued their treatment during follow-up with a median exposure duration of 16 weeks (IQR: 4-24): 11 due to primary non response, 3 due to secondary loss of response, 7 due to adverse event (AE). Among these 21 patients, 4 patients underwent CD-related surgery (2 intestinal resections and 2 diverting ostomies) after a median duration of 15 weeks (IQR: 11-24), while the others switched to another medical therapy. In total, 21% (11/52) patients required hospitalization within 24 weeks.

Twenty-seven AEs were reported in 19 (37%) patients, with 7 leading to treatment discontinuation (2 allergic skin rash, 1 severe acne, 1 folliculitis, 1 lip oedema, 1 severe stomatitis and 1 loss of appetite). The most common reported AEs were herpes simplex reactivation, respiratory tract infection, cutaneous reactions and acne. No herpes zoster infection, thrombotic or cardiovascular event were reported.

Conclusion: In this real-world cohort of highly refractory CD patients, UPA effectively induced steroid-free clinical remission and endoscopic remission by week 24 and was relatively well tolerated with respect to adverse events.

Disclosure: Dr Anneline Cremer has received lecture and advisory board fees from Galapagos, Abbvie, Janssen (2009-2014); lecture fees from Celltrion (2019-2024), Pfizer (2018-2023); advisory board fees from Takeda (2018-2023).

Dr Denis Franchimont has received lecture and/or advisory board fees from Abbvie, AstraZeneca, Dr. Falk Pharma, Ferring, Janssen, Mundipharma, MSD, Pfizer, Takeda, Amgen and research grants from Abbvie, Janssen, Takeda, Celltrion and Amgen (2019-2024).

Introduction: In this induction period analysis of the FilgoColitis study, we report on clinical effectiveness and psychosocial outcomes in ulcer-

ative colitis (UC) patients newly initiated on filgotinib (FIL) therapy in a real-world setting. In addition, this study attempts to define novel patient-based outcomes monitored by wearable devices.

Aims & Methods: FilgoColitis is a prospective, multi-centre, non-interventional, 24-month observational study in patients with active UC newly initiated on FIL therapy. The study evaluates patients with active UC receiving FIL in terms of disease activity (pMayo score), quality of life (QoL), and - in a subset - physical activity using two different wearable devices (Garmin® smartwatch and SensMotion® accelerometer). pMayo-defined clinical remission was related to physical activity (steps), mean heart rate, and stress levels in UC patients with complete wearable data available for the four days immediately following both baseline and week 10 (n=32). Data were considered complete if more than 50% of daily data were recorded from 6 am to 10 pm on at least 3 out of 4 days.

Results: The study enrolled 202 patients with UC who were newly treated with FIL. Six patients were excluded due to incomplete baseline data. Out of the participants with complete baseline data (n=196), 106 (54.1%) used at least one wearable device during the study. To validate the smartwatch, all steps measured in parallel by both the smartwatch and the conventional accelerometer system were compared halfway through the recruitment period and showed good agreement with a positive correlation of 0.88 (p<0.001). 168 patients with complete baseline and week 10 data were available for the induction period (week 10) analysis. Of these, 61.3% were male, and the median time since diagnosis was 8.0 years. Prior to treatment with FIL, 85.1% of patients had received biologic or small molecule therapies, and 54.8% had used immunosuppressants. After 10 weeks of induction therapy with FIL, a clinical response rate of 50.9% and a clinical remission rate of 29.2% were observed (Tab. 1). Clinical remission was 36.0% in biologic-naïve (n=25) and 28.0% in biologic-experienced patients (n=143) (p=0.564). The median baseline score on the EQ-VAS was 60, which increased to 75 by week 10, reflecting a significant improvement in QoL (p<0.001). There was no association between general biometric stress readings or step counts and clinical remission at week 10. However, heart rate at week 10 was significantly associated with clinical remission status, with a mean heart rate of 71.5 beats per minute (bpm) observed in patients in remission and 85.4 bpm in those not in remission (p=0.005). Sensitivity analysis identified a threshold of 80 bpm as optimal for discriminating clinical remission status, yielding a specificity of 0.778 and a sensitivity of 0.857.

Conclusion: In this real-world study, filgotinib demonstrated a response rate of 51% and a clinical remission rate of 29% in active UC at week 10. Using wearable device data, heart rate was identified as a suitable discriminator for categorising remission status. Subsequent analyses over the maintenance period will evaluate the utility of heart rate and additional wearable parameters in assessing clinical remission.

Outcome at week 10	all	bio-naïve	bio-experienced	p
n	168	25	143	
Clinical response modified, n (%)	84 (50.9)	14 (58.3)	70 (49.6)	0.571
Clinical remission, n (%)	49 (29.2)	9 (36.0)	40 (28.0)	0.564
Steroid-free remission, n (%)	43 (25.6)	8 (32.0)	35 (24.5)	0.584

Introduction: Filgotinib (FIL) is an oral, JAK1 preferential inhibitor approved for the treatment of ulcerative colitis (UC). Although the clinical efficacy of FIL in UC has been demonstrated in the SELECTION trial,¹ real-world data are limited.

Aims & Methods: In total, 600 adult patients with moderately to severely active UC who initiate FIL treatment in routine clinical care will be enrolled in GALOCEAN (NCT05817942), an ongoing, European, multi-site, prospective, observational study. Here, we report baseline characteristics of the first 100 enrolled patients and effectiveness data from patients who reached week 10. Baseline demographics, disease characteristics, prior UC-related treatment and reasons for starting FIL were collected. At week 10, mean changes from baseline (CFBs) in the partial Mayo Clinic Score (pMCS) and the PRO-2 score, and the proportions of patients in pMCS remission (pMCS of ≤ 2) or PRO-2 remission (rectal bleeding subscore of 0 and stool frequency subscore of ≤ 1) were assessed. Mean CFBs at week 10 in patient-reported outcomes (Short Inflammatory Bowel Disease Questionnaire [SIBDQ], Urgency Numerical Rating Scale [NRS] and Functional Assessment of Chronic Illness Therapy-Fatigue [FACIT-Fatigue] scores) were also calculated. Safety was evaluated by documenting adverse events.

Results: As of January 2024, 100 patients (FIL 200 mg, 97% [97/100]; FIL 100 mg, 3% [3/100]) were enrolled, and had baseline data available; out of which 55 reached week 10. Baseline characteristics are shown in the **Table**. In total, 70% of patients (67/96) had up to moderate disease activity (pMCS of ≤ 6) and 30% (29/96) had severe disease activity (pMCS of ≥ 7) at baseline; 42% (42/100) were biologic-naïve. The most common cardiovascular risk factor was active or prior smoking (37% [37/100]). FIL was used as monotherapy in 47% of patients (47/100). At week 10, the mean (standard deviation [SD]) CFB in the pMCS was -2.7 (2.5; n=43), and 58% of patients (25/43) achieved pMCS remission. The mean (SD) CFB in the PRO-2 score at week 10 was -1.8 (1.7; n=46), and 72% of patients (33/46) achieved PRO-2 remission. Mean (SD) CFBs in patient-reported outcomes at week 10 were 10.1 (12.4; n=42) for the SIBDQ score, -1.3 (2.8; n=38) for the Urgency NRS score and 4.0 (9.3; n=42) for the FACIT-Fatigue score. Overall, 10 patients discontinued FIL because of adverse events, lack of effectiveness or physician decision. No new safety signals were identified. **Conclusion:** In this first interim report of GALOCEAN, week 10 data show that FIL improves symptoms in patients with UC in real-world clinical practice and has beneficial effects on health-related quality of life and fatigue. GALOCEAN is ongoing and long-term data with higher patient numbers will be evaluated to further characterize the real-world effectiveness of FIL in UC.

Characteristic	Total ^a (N=100)
Age, years, median (min-max)	37.0 (19-67)

TOFACITINIB VERSUS VEDOLIZUMAB IN ULCERATIVE COLITIS WITH PRIOR ANTI-TNF FAILURE: A SYSTEMATIC REVIEW AND META-ANALYSIS

N.J. Milioli¹, V. Antunes², O. Martins³, T. Correa⁴, A.A. Prata⁵, A.C. Coan⁵, A.M. Reis⁶, E. Bulhões⁷, P. Romeiro⁸, M.V. Fernandes²

Introduction:

Anti-TNF agents play a significant role in the induction and maintenance therapy of moderate to severe ulcerative colitis. However, at least 30% of patients experience loss of response within the first year of treatment.

Aims & Methods: This study aims to compare Tofacitinib versus Vedolizumab in patients with ulcerative colitis in the setting of previous anti-TNF failure. We performed a systematic review in PubMed, Embase and Cochrane databases, searching for randomized and non-randomized studies comparing Tofacitinib versus Vedolizumab in this population. The primary outcome was colectomy rate. The secondary outcomes were thromboembolic event rate and infectious incidence. The odds ratio (OR) was used for binary outcomes with their respective 95% confidence interval (CI). Heterogeneity was assessed using the Cochran Q test and I² statistics.

Results: The meta-analyses included 6 studies and 2,241 patients. There was a significant difference favoring Vedolizumab in colectomy rate (OR 2.03; 95% CI 1.30 to 3.16, p=0.002; I²=0%). There were no difference in thromboembolic event rate (OR 0.90; 95% CI 0.39 to 2.06; p=0.798; I²=0%) and infection incidence (OR 0.83; 95% CI 0.56 to 1.25; p=0.378; I²=0%).

Conclusion: In patients with ulcerative colitis with prior anti-TNF failure, tofacitinib showed higher colectomy rate compared to vedolizumab, with no difference in thromboembolic and infectious events between both groups. Considering this, vedolizumab seems to be a reasonable option in this population.

Introduction: Inflammatory bowel disease (IBD) has been associated with increased major adverse cardiac events (MACE). The ORAL Surveillance study reported increased risks of MACE in older adults with rheumatoid arthritis and cardiovascular (CV) risk factors (RFs) when treated with a Janus kinase inhibitor (JAKi) versus anti-tumor necrosis factor (anti-TNF) therapy. These results have prompted revisions in the guidelines on the utilization of JAKi in patients with IBD. However, the mechanisms behind the reported adverse outcomes associated with JAKi have not been fully elucidated. Microvascular dysfunction (MVD) is an independent, well-defined predictor of future MACE. Nitric oxide (NO) serves as the primary vasodilatory metabolite in healthy microcirculation, but in pathologic states like coronary artery disease (CAD) and diabetes mellitus (DM), this role shifts to hydrogen peroxide (H₂O₂).

Aims & Methods: We aimed to investigate the mechanistic effects of JAKi and anti-TNF drugs on microvascular endothelial function. Flow-mediated dilation (FMD), pharmacologically induced endothelial-dependent dilation to acetylcholine (ACh), and smooth muscle-dependent dilation to papaverine (ex vivo) were examined in vessels from healthy (≤ 3) and high-risk (≥ 4 CV RFs) subjects. To assess the effect of NO synthase blockade and H₂O₂ scavenging, we incubated vessels with L-NAME and PEG-Catalase (peg-cat), respectively. Isolated arterioles from surgical discard tissue were incubated in an endothelial culture medium containing vehicle (control), JAKi (Tofacitinib Citrate, CP-690550, Selleckchem), or anti-TNF (Infliximab, Y0002047, Sigma-Aldrich). Video microscopy was used to measure dilator function. Data are expressed as % max. diameter $\pm$ SE for n = 3-5 per condition, *p<0.05, **p<0.01, ***p<0.001. Statistical significance was established using two-way ANOVA.

Results: In isolated vessels from both healthy and high-risk subjects, neither anti-TNF nor JAKi treatments impaired FMD, ACh-mediated dilation, or papaverine-mediated dilation when compared to historic controls. Interestingly, in healthy vessels treated with JAKi, FMD was significantly blocked by peg-cat (at 100 cmH₂O, JAKi: 87 $\pm$ 10%, n = 3 vs. JAKi + peg-cat: 58 $\pm$ 12%, n = 3, p = 0.01), suggesting a mechanistic switch from NO to pathologic H₂O₂-mediated vasodilation, similar to the phenotype observed in patients with CAD. Additionally, treatment with anti-TNF partially restored L-NAME-inhibitable dilation in vessels from individuals with elevated CV risk (at 100 cmH₂O, anti-TNF: 68 $\pm$ 8%, n = 5 vs. anti-TNF + L-NAME: 36 $\pm$ 13%, n = 5, p = 0.116), suggesting a potential beneficial

effect on microvascular function. Results did not change with sub-group analysis of patients with and without CAD and DM, both recognized factors impacting MVD.

Conclusion: Our preliminary findings suggest that JAKi and anti-TNF drugs may have different mechanistic effects on microvascular endothelial function in vessels from healthy and high-risk patients. Further studies examining the impact of IBD medications on microvascular endothelial function pathways may provide a novel approach to guide therapeutic management in IBD patients with varying CV profiles.

Introduction: Upadacitinib (UPA) is an oral, reversible Janus kinase inhibitor (JAKi) approved for the treatment of moderately to severely active Crohn's disease (CD) and ulcerative colitis (UC).¹⁻⁴ Abnormal levels of liver enzymes are frequently encountered in patients with inflammatory bowel disease. However, data on liver enzyme elevations in UC and CD patients treated with JAKi are limited.

Aims & Methods: This post hoc analysis evaluated changes in liver enzymes over time in phase 3 trials of UPA in CD (U-EXCEL, U-EXCEED, U-ENDURE) and UC (U-ACCOMPLISH, U-ACHIEVE). Patients were randomized 2:1 to receive once-daily (QD) UPA 45 mg (UPA45) or placebo (PBO) induction therapy for 12 weeks (wks) in the CD trials and 8 wks in the UC trials.^{3,4} Patients who achieved clinical response to UPA induction therapy were rerandomized (1:1:1) to PBO, UPA 15 mg (UPA15), or UPA 30 mg (UPA30) QD for the 52-wk maintenance studies.^{3,4} Data from the induction studies were pooled, as were data from the maintenance studies. Least-squared (LS) mean changes from baseline (BL) in alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and total bilirubin (TBili) were calculated using ANCOVA models with treatment as a main factor, and BL and indication as covariates for induction and maintenance periods. The proportions of UPA-treated patients with Grade 3-4 liver enzyme elevations (ALT, AST, and ALP: >5.0 x upper limit normal [ULN]; TBili: >3.0 x ULN) were assessed.

Results: This analysis included 2,118 patients. At induction, BL mean [SD] ALT (PBO 19.4 [15.7] U/L; UPA45 18.2 [15.4] U/L, AST (PBO 19.5 [26.4] U/L; UPA45 17.8 [13.4] U/L, ALP (PBO 74.5 [25.8] U/L; UPA45 74.7 [35.2] U/L, and TBili (PBO 6.9 [4.4] μ mol/L; UPA45 6.8 [4.0] μ mol/L) were similar across treatment arms and within normal ranges. LS mean changes [SE] from BL in ALT, AST, ALP, and TBili were 4.7 [0.4] U/L, 4.7 [0.5] U/L, -8.7 [0.5] U/L, and 1.8 [0.1] μ mol/L, respectively, by wk 4 of UPA induction and remained relatively stable across all treatment groups through

wk52 of maintenance (Table). Incidences of Grade 3 or 4 elevations in liver enzymes were low throughout induction and maintenance (ALT: UPA45 1.1%, UPA15 2.1%, UPA30 1.0%; AST: UPA45 1.4%, UPA15 1.3%, UPA30 1.5%; ALP: UPA45 <0.1%, UPA15 0%, UPA30 0.2%; TBili: UPA45 0.4%, UPA15 0.4%, UPA30 0.6%). There were no events of drug-induced liver injury (DILI) in CD; 1 event was reported in UPA45 in UC induction, 1 event each in UPA15 and UPA30 in UC maintenance, all were nonserious and possibly attributed to other underlying conditions (i.e., alcohol) and/or concomitant medications (i.e., isoniazid, estrogen-containing contraceptive) (see Table footnotes).

Induction, LS Mean Change (SE)			Maintenance, LS Mean Change (SE)		
Parameter Timepoint	PBO (n = 725)	UPA45 (n = 1393)	Parameter Timepoint	PBO (n = 468)	UPA15 (n = 471) UPA30 (n = 480)

Week 4	0.0 (0.1)	1.8 (0.1)	Week 12	0.4 (0.2)	1.9 (0.2)
Week 8	0.6 (0.2)	2.5 (0.1)	Week 52	3.0 (0.6)	5.5 (0.4)
DILI, n (%)	n = 378	n = 719	DILI, n (%)	n = 245	n = 250
[SSA%]	0	1 (0.1) [0.2] ^a	[SSA%]	0	1 (0.4) [0.4] ^b

ALT, alanine aminotransferase; AST, aspartate aminotransferase; ALP, alkaline phosphatase; CD, Crohn's disease; DILI, drug-induced liver injury; LS, least square; PBO, placebo; SSA, study site adjusted; TBili, total bilirubin; UC, ulcerative colitis; UPA, upadacitinib.

Pooled UC+CD data are reported as LS mean change from baseline (standard error). Baseline is defined as the last nonmissing observation before their first dose of study drug. The denominators for DILI are from patients in the UC program only, as there were no reports in CD.

^a Liver damage due to concomitant isoniazid use for latent tuberculosis in 52-year-old female with 24 years of UC and was a current alcohol user. Event was reported on day 15 of UPA exposure.

^b Drug-induced hepatitis moderate in severity in 32-year-old male with 11 years of UC who was receiving concomitant Mesalazine medication and was a former alcohol user. Event was reported on day 140 of UPA exposure. Study drug was interrupted.

^c Drug-induced hepatopathy mild in severity in 28-year-old female with 6 years of UC who was receiving concomitant Pentasa and Triquilar medications. Event was reported on day 259 of UPA exposure. Patient withdrew from treatment.

Conclusion: Patients with moderately to severely active CD or UC receiving UPA experienced early changes in liver enzymes, which remained stable thereafter. Grade 3-4 elevations were rare and nonserious. Further evaluations of these liver enzyme changes and association with UPA benefit/risk over long-term extension studies are warranted.

Introduction: Oral corticosteroids remain the treatment of choice for moderately active ulcerative colitis (UC). However, only 30-60% of patients achieved clinical remission in controlled studies. In severe systemic diseases such as systemic lupus, the administration of high-dose intravenous methyl-prednisolone bolus accelerates and enhances clinical response.

Aims & Methods: Aims: To assess the impact of adding high-dose intravenous methyl-prednisolone bolus to oral corticosteroids for the treatment of moderately active UC.

Methods: Prospective, multicentre, controlled, randomised and open study. To be included, patients had to fulfil all the following criteria: 1) moderately active UC (complete Mayo score -cMS- of 6-10); 2) distal or extensive UC extent; 3) naïve to immunosuppressant and biological agents; and 4) absence of steroid-dependency criteria. Patients were randomised to receive either oral prednisone 60mg/day (ORAL) or the same regimen preceded by a 500mg intravenous bolus of methyl-prednisolone for three days (BOLUS). Patients were stratified according to UC onset or not and baseline oral mesalazine use. Oral prednisone regimen included a tapering schedule from week 2 to week 8. Once reaching the prednisone dose of 20 mg/day all patients started 2g/day of oral mesalazine. The main endpoint was clinical and endoscopic remission (cMS <3 with no value >1) at weeks 8 and 54, without needing rescue therapy or additional corticosteroid exposure.

Results: A total of 75 patients were included (39 in ORAL group, 36 in BOLUS group), with 24% at UC onset, 51% having extensive disease, 68% on maintenance oral mesalazine and 31% having received corticosteroids previously. Baseline cMS was 9 (7-9), C-reactive protein 9.25 mg/L (3.85-

20.17), and serum albumin 39.5 g/L (36.6-42.9), with no significant differences in clinical-epidemiological characteristics between both treatment groups. Overall, 48% (36 patients) achieved clinical-endoscopic remission at week 8 and 28% (21 patients) at both weeks 8 and 54 without needing additional steroid courses or rescue treatments. Among these, 11/36 (30.5%) were in the BOLUS group and 10/39 (25.6%) were in the ORAL group (P = 0.636). No significant differences between treatment groups were found in secondary endpoints including clinical-endoscopic remission at week 8 (58.3% vs. 38.5%; p = 0.085), clinical remission at week 54 (38.9% vs. 35.9%; P = 0.789), and endoscopic remission at week 54 (36.1% vs. 30.8%; P = 0.624).

Conclusion: The addition of three high-dose intravenous corticosteroids at the beginning of a conventional oral prednisone regimen does not improve the efficacy of treating moderately active UC in short nor in the medium term.

Disclosure: Nothing to disclose.

Introduction: Patients enrolled in randomised controlled trials (RCT) of advanced therapeutics in inflammatory bowel disease (IBD) may differ from the target population of patients given these same drugs in routine practice. Prior research from 2012 indicated that only approximately a third of patients would theoretically qualify for enrolment in an RCT (1). We aimed to re-evaluate the overlap between patients in routine practice and those in contemporary RCTs.

Aims & Methods: We evaluated all patients with active IBD at our institution who were considered for treatment with a biologic or small molecule (both de novo and switching). Their characteristics were compared against inclusion and exclusion criteria of recently completed or ongoing RCTs: ozanimod, upadacitinib, risankizumab, golimumab-guselkumab, guselkumab (Crohn's disease [CD] only), filgotinib, mirikizumab, and etrasimod (ulcerative colitis [UC] only for the latter three drugs). We calculated the percentage of patients ineligible for all evaluated trials and identified the commonest criteria for ineligibility.

Trial	Crohn's disease (n = 155)	Ulcerative colitis (n = 131)
Ozanimod	46 (29.7%)	22 (14.2%)
Upadacitinib	24 (15.5%)	34 (21.9%)
Risankizumab	17 (11.0%)	42 (27.1%)
Guselkumab	24 (15.5%)	/
Golimumab-guselkumab	13 (8.4%)	32 (20.7%)
Filgotinib	/	11 (7.1%)
Mirikizumab	/	19 (12.3%)
Etrasimod	/	45 (29.0%)
At least one trial	53 (34.2%)	62 (47.3%)

Table 1. Number of patients (n, %) with inflammatory bowel disease eligible for participation in a randomized clinical trial.

Results: We evaluated 286 patients (155 CD, 131 UC); 16 additional patients with IBD unclassified were ineligible for trial participation by default. Among patients with CD, 34.2% (53/155) would have been eligible

for participation in at least one RCT; among patients with UC, 47.3% (62/131) would have been eligible for participation in at least one RCT (Table 1). Patients with CD would have been excluded mainly due to the presence of stricturing or penetrating disease, the presence of ostomies, comorbidities, including history of malignancy, and insufficient symptoms despite endoscopic activity. Patients with UC would have been excluded mainly due to insufficient symptoms despite endoscopic activity, ulcerative proctitis, newly diagnosed disease, and comorbidities, including history of malignancy.

Conclusion: Only a minority of patients with IBD from routine practice would be eligible for participation in contemporary RCTs, although the percentage has increased for patients with UC compared to past studies.

Introduction: The influence of environmental factors in the course of inflammatory bowel diseases (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), is unclear.

Aims & Methods: We aimed to investigate the role of environmental factors in disease activity, severity, and initial course of IBD.

Since May 1st, 2021, all adult and pediatric patients with incident IBD within a catchment area encompassing 20% of the Danish population were enrolled in the prospective population-based Copenhagen IBD Inception Cohort.¹ Upon diagnosis, all adult patients diagnosed between May 2021 and May 2023 were asked to report environmental factors using the International Organisation of IBD (IOIBD) and HeartDiet questionnaires.

A severe disease course was defined as a composite of a need for either oral glucocorticoids, immunomodulators, biologics, or intestinal resection within three months of disease. Severe disease activity was defined either endoscopically (UC: Mayo Endoscopic Score=3, CD: Simple Endoscopic Score-CD>16) or as a composite of biochemical activity (f-calprotectin>1800 µg/ g or C-reactive protein > 10 mg/L) and clinical activity (UC: Simple Clinical Colitis Activity Index (SCCAI)>10, CD: Harvey-Bradshaw Index (HBI)>7).

Clinical remission was defined as SCCAI<3 or HBI<5 points. All findings were adjusted for gender, age, and disease phenotype in multivariable logistical analysis yielding adjusted odds ratios (aOR (95% confidence interval)).

Results: The population consisted of 208 and 128 patients with incident UC and CD (67.5% and 63.1% of the original cohort), respectively, who completed the questionnaires within a median of 1.3 months (IQR 0.4 – 3.4 months) from diagnosis. No clinical differences were between participants and non-participants. During six months of follow-up, 128 (61.5%) and 77 (60.2%) patients with UC and CD, respectively, achieved clinical remission. In patients with UC, low intake of saturated fatty acids was associated with reduced probability of achieving clinical remission at follow-up (aOR= 0.42 [0.18;0.95]). In patients with CD, a high intake of whole meal bread was significantly associated with a reduced risk of severe activity (aOR=0.40 [0.16;0.98]), while high intake of fruits (aOR=0.27 [0.07;0.99]), vegetables (aOR=0.27 [0.09;0.80]), or fibers (aOR=0.30 [0.09;0.96]) were associated with lower risk of stricturing or penetrating phenotypes.

A severe disease course of UC was significantly and inversely associated with active smoking (aOR=0.28 [0.08;0.95]), intake of minced meat (aOR=0.38, [0.15;0.97]), and ultra-processed food (aOR=0.22 [0.06;0.78]). Conversely, minced meat was associated with elevated risk of a severe course of CD (aOR=3.59 [1.41;9.10]). In addition, active smoking was associated with increased risk of CD-related hospitalization (aOR=11.89

[2.53;55.92]) and stricturing phenotype (aOR=5.28 [1.76;15.85]). On the other hand, previous pregnancy (aOR=0.28 [0.09;0.93]) was associated with a reduced risk of a severe course of CD.

Among childhood factors, appendectomy was associated with increased risk of UC-related hospitalization (aOR=5.46 [1.05;28.34]), CD-related hospitalizations (aOR=11.89 [2.53;55.92]), and CD-related resections (aOR=19.48 [4.20;90.35]).

Conclusion: In conclusion, our prospective population-based study unveiled distinct environmental exposures to be associated with important clinical endpoints in UC and CD. These findings hold clinical value as they inform personalized patient counseling on lifestyle factors that might influence outcomes of IBD.

PREGNANCY OUTCOMES IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE IN THREE UNIVERSITY MEDICAL CENTERS IN THE NETHERLANDS

D.G. Bouwknegt¹, G. Dijkstra¹, W.A. van Dop², C.J. van der Woude³, M.C. Visschedijk¹

¹University Medical Center Groningen, Gastroenterology and Hepatology, Groningen, Netherlands, ²Radboud University Medical Center, Gastroenterology and Hepatology, Nijmegen, Netherlands, ³Erasmus University Medical Center, Gastroenterology and Hepatology, Rotterdam, Netherlands

Introduction: As inflammatory bowel disease (IBD) is frequently diagnosed in young adults, the disease often coincides with pregnancy. About one in four female patients will have their first pregnancy after diagnosis. Current guidelines advise treatment through specialized clinics for IBD patients wishing to conceive, which are increasingly implemented. However, recent outcome data from these centers is scarce. In this study we therefore describe the pregnancy-course in three specialized Dutch IBD university clinics.

Aims & Methods: For this multicenter, retrospective cohort study, all adult female IBD-patients who had been pregnant during treatment in any of the three participating Dutch university medical centers between the inception of the respective electronic patient records and 2022 were included. Data on patient- and disease characteristics, lab values, medication usage and pregnancy outcomes was extracted from the electronic pa-

tient records. Topics relevant to pregnancy were logged, including intoxications, the use of folic acid and vitamin D, and gestational weight gain.

Results: Data was collected on 620 women who had been pregnant in the study period, including 376 (60.6%) with Crohn's disease (CD), 230 (37.1%) with ulcerative colitis (UC), and 13 (2.1%) with inflammatory bowel disease unclassified (IBDU). Of the CD-patients, 68 (18.1%) had a history of perianal disease. The mean age at conception of the first pregnancy was 29.9 years. Altogether, 983 pregnancies were included, of which 10.3% was conceived using assisted reproductive technologies, including in vitro fertilization (IVF) in 3.6% of pregnancies. During 9.8% of pregnancies, the mother actively smoked tobacco at conception. Medication was used during 71.0% of pregnancies, most often consisting of thiopurines (27.1%) and amino salicylates (24.4%). Appropriate gestational weight gain was achieved in 31.1% of pregnancies. 152 (15.5%) pregnancies resulted in miscarriage, 12 (1.2%) pregnancies were ectopic. In the remaining pregnancies, 511 (62.4%) newborns were delivered vaginally. A caesarean section (CS) was performed in 234 cases (23.8%). Overall, 54 mothers (23.1%) who underwent a CS had perianal disease. An adverse pregnancy outcome was noted in 159 (21.3%) of pregnancies, including low birth weight in 78 (10.5%), prematurity in 85 (11.4%) and dysmaturity in 89 (11.9%). Adverse outcomes occurred more often in the group of women who experienced disease activity in any point during pregnancy, but this difference was not statistically significant (30.8% vs 21.7%, p=0.120). Two patients developed deep venous thromboembolism during or within six weeks after pregnancy.

Conclusion: In IBD the mean age at conception and the rate of pregnancies conceived using IVF were comparable with the general Dutch population. A CS was performed more frequently in this cohort when compared to healthy pregnancies in the Netherlands (23.8% vs 17.6%). In these specialized centers low birth weight (10.5% vs 5.7%), prematurity (11.4% vs 6.6%) and dysmaturity (11.9% vs 9.7%) occurred more often in comparison to the known rates in Dutch pregnancies, emphasizing that adequate counseling before and during pregnancy in IBD is essential.

Disclosure: Nothing to disclose.

Introduction: Inflammatory bowel disease (IBD) often affects patients during their reproductive years. The management of patients wishing to conceive or during pregnancy requires specialized counseling.

Aims & Methods: Our aim was to have a global perspective on the management of IBD by gastroenterologists (GIs) during preconception, pregnancy, breastfeeding and neonatal period.

An anonymous survey (75 questions) was developed to investigate different facets of clinical practice concerning the management of pregnant and breastfeeding in patients with IBD. A national representative from each European country, USA, Latin America, Australia and New Zealand was selected to distribute the survey to their GIs colleagues who treat IBD patients (irrespective of their experience).

Results: A total of 856 GIs from 36 countries participated in the survey. Among the participants, 63% had over a decade of experience as GIs, and 61% identified themselves as IBD specialists. The most relevant survey results and sub-analyses based on expertise are presented in tables 1 and 2. In the management of pregnant patients in remission, treatment discontinuation occurred either consistently or occasionally as follows: 20% thiopurines, 37% vedolizumab, 31% ustekinumab, and 96% small molecules. Notably, 13% did not always discontinue small molecules in patients contemplating pregnancy. Safety was the main reason for discontinuing IBD therapy during pregnancy. Contrary to the recommendations in clinical practice guidelines, many GIs avoid starting oral or rectal budesonide, anti-TNF, vedolizumab or ustekinumab during a disease flare. Further, a third of GIs would start thiopurines for a flare during pregnancy. Moreover, 13% will never perform a colonoscopy in a pregnant patient to guide decision making. Half of GIs implemented a dedicated outpatient follow-up program for pregnant patients in remission, with 87% enrolling all pregnant patients in this program. Concerning breastfeeding, 14% believed that all drugs can be used while breastfeeding. Regarding offspring's vaccination, about 20% recommend against the administration of non-live vaccines and only 50% recommended avoiding live vaccines during the first 12 months for children exposed to anti-TNF in-utero. Among those GIs who recommended delaying vaccines in such cases, only 41% recommended testing the infant for detectable anti-TNF levels if live vaccines were required. Among the surveyed GIs, only a minority had a referral obstetrician, and only 35% referred patients with active or complicated IBD, while 45% had a referral paediatrician with expertise in IBD. The main results regarding the medical management and monitoring of IBD during pregnancy, as well as advice on birth outcomes, breastfeeding, and vaccination, are detailed in Table 1.

Conclusion: The management of IBD during pregnancy, lactation, and neonatal period is notably suboptimal, even among GIs specifically dedicated to IBD. It is crucial to address this current need and implement urgent educational measures in this area.

Questions	Global N=856	By expertise		
		IBD specialists N=315	General GIs N=521	P
Pregnant patients in remission				
Discontinued of different types of drugs (always or sometimes), n (%)				
- Thiopurines	162 (20)	79 (15)	79 (27)	<0.001

Hannah Gordon has received speaker fees from Janssen, Ferring, AbbVie, IBDscope and consultancy fees from Galapagos

Paulo Kotze has receive consultancy and speaking honorarium for Abbvie, Janssen, Pfizer and Takeda.

Andreas Blesl has served as speaker, consultant, and advisory member for or has received research funding from Abbvie, Aengus, Boston Scientific, Bristol-Myers Squibb, Dr. Falk Pharma, Genericon, Gilead, Janssen, Lilly, MSD, Olympus, Pfizer, Takeda, Vifo

Ignacio Catalán-Serra has received research grants and/or speaker and advisory fees from: Tillots, Takeda, Ferring, Elli Lilly, Bristol-Myers-Squidd, Janssen and Abbvie

Peter Bossuyt has received financial support for research: AbbVie, Amgen, Janssen, Viatrix, Pfizer. Lecture fees: AbbVie, Bristol Myers Squibb, CAG, Celltrion, EPGS, Galapagos, Globalport, Janssen, Lilly, Materia Prima, Pentax, Scope, Takeda. Advisory board fees: AbbVie, Arena, Bristol Myers Squibb, Celltrion, CIRC, Dr Falk Benelux, Galapagos, Janssen, Eli Lilly, Pentax, PSI-CRO, Roche, Takeda, Tetrameros

Ariella Bar Gil Shitrit reports consulting/advisory fees from Takeda, Janssen, Neopharm Pfizer and AbbVie; Speaking and teaching fees from Takeda, Janssen, AbbVie, Neopharm, Rafa, BMS, Lilly and Pfizer, and research support from Takeda and Janssen.

Paulina Molander has received speaker and consultancy fees from Abbvie, Orion Pharma, Pfizer, Sandoz, Takeda, Tillotts Pharma, and advisory board member fees from BMS, Gilead and Janssen-Cilag

G Mantzaris: has served as advisory board member for AbbVie, Celgene, Celtrion, Ferring, Genesis, Hospira, Janssen, Millennium Pharmaceuticals, Merck Sharp & Dohme, Mylan, Pharmacosmos, Pfizer, Takeda, and Vianex;

has served as a speaker for AbbVie, Angelini, Falk Pharma, Ferring, Galenica, Cenesys, Hospira, Janssen, Merck Sharp & Dohme, Omega Pharma, Takeda, and Vianex; has served as a consultant for Merck Sharp & Dohme and Takeda; and has received research support from AbbVie, Galenica, Genesis, Menarini Group, and Merck Sharp & Dohme.

Pascal Juillerat has received research grant from Vifor Pharma, consulting/ Board/speaker from AbbVie, Arena, Amgen, BMS, Ferring, Gilead, Janssen, Lilly, MSD, Pfizer, Pierre Fabre, Roche, Sandoz, Takeda, Tillots, UCB Pharma.

Krisztina B. Gecse has received research grants from Abbvie, Pfizer Inc, Celltrion and Galapagos, consultancy fees and speaker's honoraria from AbbVie, Celltrion, Ferring, Galapagos, Immunic Therapeutics, Janssen Pharmaceuticals, Pfizer Inc., Samsung Bioepis, Takeda and Tillotts.

Pär Mirelyd has received paid lectures from Abbvie, Tillotts, Galapagos, Janssen and Pfizer

Uma Mahadevan has received consultant fees from Abbvie, Arena, BMS, Boehringer Ingelheim, Celltrion, Enveda, Gilead, Janssen, Lilly, Merck/Prometheus Laboratories, Pfizer, Rani Therapeutics, Roivant, Takeda.

Beatriz Iade has served as speaker from Abbvie and Janssen.

Dana Duricova has received lecture fee/ consultancy from Janssen, Takeda, Abbvie, Pfizer, Ferring, Eli-Lilly

Mette Julsgaard has received research grants for other investigator-driven studies from Takeda and Novo Nordisk Foundation (grant no. NN-F23OC0081717), has received consultation fees from Ferring and Takeda, and has received speaker's fees from MSD, Ferring, Tillotts Pharma, and Takeda.

María Chaparro has served as speaker, consultant or research or education funding from MSD, Abbvie, Hospira, Pfizer, Takeda, Janssen, Ferring, Shire Pharmaceuticals, Dr. Falk Pharma, Tillotts Pharma, Biogen, Gilead and Lilly.

Introduction: Crohn's disease (CD) is a type of chronic inflammatory bowel disease (IBD) characterized by transmural granulomatous inflammation, skip lesions, and a relapsing-remitting course, which affects the entire gastrointestinal tract, from the mouth to the anus. Patients with chronic illness are at an increased risk for traumatic stress because of the medical trauma. Previous evidence suggests that many patients perceive

the chronic nature of the disease and related diagnostics and therapeutic procedures as traumatic events. Initial studies on post-traumatic stress (PTS) in patients with inflammatory bowel disease have found that approximately one-third of patients may experience significant PTS symptoms, including flashbacks, nightmares, hypervigilance, disrupted sleep, and low mood, potentially leading to the development of post-traumatic stress disorder (PTSD).

Aims & Methods: The aim of this work is to assess the moderating role of adverse childhood experiences in the relationship between CD activity and PTSD symptoms.

In this cross-sectional study, the revised version of the Impact of Event Scale (IES-R) and the Adverse Childhood Experiences (ACEs) Questionnaire were administered to consecutive CD outpatients afferent to Fondazione Policlinico Universitario "A. Gemelli", IRCCS, Rome. The clinical disease activity of patients was assessed according to the Harvey-Bradshaw index (HBI). Data were analyzed using Pearson correlation coefficients and moderated regression analyses in SPSS software (version 27).

Results: A total of 172 CD patients were included in the study, with 154 completing the IES and 148 the ACEs questionnaire. Forty-eight patients (31.2% of the sample) exhibited a score of 33 or more on the IES-R, suggestive of a PTSD. Correlation analyses revealed that ACEs scores correlated significantly with all subscales of the IES-R: intrusion ($r=.405$, $p < .001$), avoidance ($r=.348$, $p < .001$), and hyperarousal ($r=.363$, $p < .001$). Moreover, patients with higher adverse childhood experiences (i.e., with high scores on the ACEs) had significantly more severe disease activity ($r=.272$, $p < .001$). Notably, the highest scores of ACEs were observed for the items related to feeling undervalued and ignored by one's family. Further results from regression analysis demonstrated that the relationship between CD activity and the overall IES-R score was significantly stronger among patients with high ACEs scores ($b = .21$, $p < .001$) compared to those with medium ($b = .12$, $p = .005$) or low scores ($b = .06$, $p = .291$).

Conclusion: Our study revealed that ACEs play a moderating role in the relationship between disease activity and the development of PTSD symptoms in the CD patient population. Patients with higher PTS symptoms and more ACEs are less likely to be in remission and may utilize more outpatient gastrointestinal services. These findings underscore the importance of a psychological assessment to enhance the management of these patients. Intervention trials to mitigate PTS symptoms in patients with IBD are warranted.

Introduction: The highest risk factor of inflammatory bowel disease (IBD) is having a first-degree relative (FDR) with IBD. Although the prevalence of IBD in Norway is among the highest in the world, its incidence has remained steady throughout the 21st century.

Aims & Methods: In this era of stable incidence, we wanted to explore the role of a positive family history of IBD. The rate of having at least one FDR with IBD in the adult IBD population was estimated in two population-based IBD incidence cohorts conducted in South-Eastern Norway. One in 1990-1994 (IBSEN) (0.9 M inhabitants in 1992) and the second 30 years later, in 2017-2019 (IBSEN III) (2.95 M inhabitants in 2017). We compared the phenotype of IBD, age at diagnosis (AAD) with standard deviation, the distribution of disease and severity of IBD, between sporadic and familial cases of IBD in the two cohorts. Severe disease was defined as extensive colitis in Ulcerative colitis (UC), and the presence of perianal, stricturing, or penetrating disease in Crohn's disease (CD). Further, those who reported more than one FDR with IBD in the IBSEN III cohort were invited to participate in a multiplex-family IBD study. In this multiplex-family cohort, we explored the generational differences in AAD, the severity of disease, and the association between the length of shared household and the phenotype of IBD. Chi-square and t-test were used for categorical and continuous variables, respectively. Tests of equal proportions were performed to compare the rate of familial IBD in the IBSEN and IBSEN III cohorts.

Results: Overall 785 adults aged >18 years were included in the IBSEN cohort (1990-1994) and 1561 in the IBSEN III cohort (2017-2019), of whom 7.3 % (57) and 10.9% (170) reported a positive family history of IBD, respec-

tively. The rate of familial IBD increased by 49.3% ($p=0.008$) over 30 years. In the IBSEN III cohort, there were no significant differences in mean AAD between familial, 38.7 (14.5) and sporadic cases, 39.1 (15.0) of IBD ($p=0.739$), nor between mean AAD in familial CD, 39.4 (14.0) and UC, 38.4 (14.7) ($p=0.664$), compared to sporadic CD, 40.4 (15.8) ($p=0.678$) and UC, 39.2 (15.0) ($p=0.587$).

Among familial and sporadic cases of IBD, 45/170 (26.5%) and 449/1391 (32.3%) had severe disease, respectively ($p=0.124$). Of familial IBD with severe disease, 10/55 (18.2%) and 35/115 (30.4%) suffered from CD and UC, respectively ($p=0.090$).

Among sporadic cases of IBD, 87/451 (19.3%) with CD and 362/940 (38.5%) with UC suffered from severe disease ($p<0.001$). In the multiplex IBD cohort, we included 30 children and 18 parents with familial IBD. The mean AAD was 25.1 years (13.0) among the children and 33.3 years (16.5) among the parents ($p=0.063$). Eight of twenty-six children (30.8%) and 9/16 (56.3%) among the parents reported severe disease ($p=0.102$). The length of shared households within multiplex families from the initial IBD diagnosis among FDRs to subsequent diagnoses of CD or UC in others, was 11.78 years and 17.14 years, respectively ($p=0.026$).

Conclusion: The rate of a positive family history of IBD has increased substantially over thirty years, underscoring the importance of shared environmental factors for the development of the IBD diagnosis. Severe disease was associated with UC among familial cases as well as among sporadic cases of IBD. Shorter time of shared household was significantly associated with development of familial CD.

Introduction: Etrasimod is an oral, once-daily, selective sphingosine 1-phosphate (S1P)_{1,4,5} receptor modulator for the treatment of moderately to severely active ulcerative colitis (UC) and in development for the treatment of other immune-mediated inflammatory diseases. Based on animal studies at clinically relevant doses, etrasimod may cross the placenta and cause foetal harm. This analysis describes pregnancy outcomes in patients with maternal or paternal exposure to etrasimod during its clinical development.

Aims & Methods: Reports of pregnancy or partner pregnancy during etrasimod exposure were identified from all phase 1–3 completed or ongoing open-label studies up to 31 October 2023. These studies included healthy volunteers or patients with UC, Crohn's disease, atopic dermatitis, eosinophilic esophagitis or alopecia areata. In all studies, pregnancy was an exclusion criterion, women of childbearing age were required to use contraception and study drug was discontinued in any female patient that became pregnant. Pregnancy outcomes were categorised as healthy newborn, medical termination, foetal death, congenital malformation, spontaneous abortion or lost to follow-up.

Results: In total, 2091 unique patients were exposed to etrasimod in clinical trials; 593 (28.4%) were females of childbearing age (aged 16–44). There was a total of 14 pregnancies with exposure to etrasimod (nine maternal, five paternal). All pregnancy exposures were limited to the first trimester. Median (range) age of women with maternal etrasimod exposure was 28.0 (18–36) years. Estimated length of maternal etrasimod exposure (from last menstrual period until last etrasimod dose) ranged from 22 to 79 days. Of the nine maternal exposures, pregnancy outcomes were two healthy newborns, four medical terminations (two for unknown reasons, one due to an anembryonic gestation and one following “signs of a missed pregnancy”) and one each resulting in a congenital malformation (open [patent] foramen ovale), spontaneous abortion and loss to follow-up (Table). Of the five paternal exposures, there were two healthy newborns, two spontaneous abortions and one lost to follow-up (Table).

	Foetal death	Congenital malformation	Spontaneous abortion	Healthy newborn	Medical termination	Lost to follow-up
Maternal exposure, n (%) (N = 9)	0	1 (11.1) ^a	1 (11.1)	2 (22.2) ^b	4 (44.4) ^{c,d,e}	1 (11.1) ^f
Paternal exposure, n (%) (N = 5)	0	0	2 (40.0)	2 (40.0)	0	1 (20.0)

Data on pregnancy events and outcomes were taken from the Pfizer internal data warehouse on serious adverse events that included pregnancy.

^aPremature 34-week delivery due to premature rupture of membranes, open (patent) foramen ovale (heart) with circulatory failure and transient tachypnoea of the newborn, which were all considered non-serious concomitant events.

^bBoth patients had full-term birth, caesarean delivery.

^cReasons for medical termination were not known in two cases.

^dOne patient with an anembryonic gestation where umifenovir (received for a respiratory tract infection) was a co-suspected drug. Umifenovir is contraindicated for use in pregnancy.

^eOne patient was reported as having “signs of a missed pregnancy at 5 weeks and 6 days” the day prior to elective medical pregnancy termination.

^fPatient was diagnosed as having an ectopic pregnancy prior to being lost to follow-up.

N, total number of patients; n, number of patients with a given outcome.

Table. Pregnancy outcomes during the etrasimod clinical development programme.

Conclusion: Few pregnancies have been reported in the etrasimod clinical programme, with no clear trends on the risk of maternal or paternal etrasimod exposure. Ongoing etrasimod studies and larger post-marketing registries will further inform on the safety of etrasimod during pregnancy. Women of child-bearing potential should use birth control while on etrasimod.

RISK OF RAPIDLY PROGRESSIVE DISEASE COURSE IN PATIENTS WITH PEDIATRIC-ONSET ULCERATIVE COLITIS

G. D'Arcangelo¹, T. Raso¹, F. Ammattatelli¹, M. Distante¹, S. Rotulo¹, F. Zucconi¹, M. Aloï¹

¹Sapienza University of Rome, Pediatric Gastroenterology Unit, Rome, Italy

Contact E-Mail Address: giuliadarcangelo87@gmail.com

Introduction: Ulcerative colitis (UC) disease course is unpredictable at the diagnosis and its management is still based on a "one-size-fits-all" approach.

Aims & Methods: We aimed to investigate the predictive factors of a rapidly progressive disease course in pediatric UC.

This was a retrospective case-control study conducted at the Pediatric Gastroenterology Unit of Umberto I Hospital in Rome. We included newly diagnosed UC patients aged < 18 years, with a minimum follow-up of 24 months. Demographic data, clinical features, laboratory, endoscopic and histologic findings at the diagnosis were collected and compared between patients with indolent UC and those with a rapidly progressive (RP) course. Children were classified as having a RP course if they experienced at least one of the following within the first 24 months after diagnosis: acute severe colitis, need for colectomy, necessity to transition to anti-TNF- α therapy, or initiation of second-line biologic therapy.

Results: One hundred-sixteen patients were included, 67 (58 %) with a RP course and 49 (42 %) with an indolent disease. RP Children had higher age (11.5 vs 9, $p=0.0008$), PUCAI (50 vs 40, $p=0.0005$) and UCEIS (4 vs 3, $p=0.002$) at the diagnosis than those with indolent course. Hemoglobin was lower in the RP group (11.5 vs 12.3 g/dL, $p=0.05$). RP children had higher rate of cecal patch at endoscopy (18 % vs 2 % $p=0.007$) and a lower rate of sclerosing cholangitis (0 vs 8.2%, $p=0.02$). No differences were observed for all other clinical, laboratory, and histologic findings. Multivariate analysis confirmed that age and the presence of a cecal patch were associated with the risk of RP course ($p=0.02$, and $p=0.04$, respectively).

Conclusion: Among the clinical and easily obtainable information at the diagnosis in children with UC, an older age at the diagnosis, along with an endoscopic finding of a cecal patch seem associated with the risk of a more aggressive disease. Such results warrant confirmation in larger prospective cohorts for a future personalized approach to UC.

Disclosure: Nothing to disclose.

Introduction: Anti-TNF are the first biologic treatment option in inflammatory bowel diseases (IBD). Few data is available on the long term risk of relapse after anti-TNF withdrawal in paediatric-onset IBD, especially at the population level.

Aims & Methods: All paediatric-onset (<17 years) IBD diagnosed between 1988 and 2011 were included in a prospective population-based study and were retrospectively followed until 2013. Among patients treated with first-line anti-TNF, the cumulative probability of relapse after anti-TNF withdrawal was evaluated using a composite outcome (intestinal resection, and/or flare-related hospitalization, and/or IBD treatment initiation, and/or active disease). Factors associated with relapse were investigated with a Cox model.

Results: Among a total of 1,344 patients (Crohn's disease (CD): $n=1,007$; Ulcerative colitis (UC): $n=337$), 562 were treated with anti-TNF. Anti-TNF was stopped in 73 patients (CD: $n=66$; UC: $n=7$) during remission defined by Harvey-Bradshaw score < 4 in CD and Mayo score ≤ 2 in UC. Among them, median time to anti-TNF initiation was 1.6 years (IQR, 0.7-4.0) and median duration of treatment was 1.0 year (0.3-1.7). The first line anti-TNF therapy was infliximab in 68 (93%) patients. At anti-TNF withdrawal, 47 (64%) patients received immunosuppressant. The cumulative probability of relapse after anti-TNF withdrawal at 1, 3 and 5 years was respectively 62%, 85% and 93%. Median delay of relapse was 9.5 months (7.5-12.0). The cumulative probability of flare-related hospitalization at 1, 3 and 5 years was respectively 7%, 7% and 8%. No patient required intestinal resection after a median follow-up of 8.7 (5.8-13.8) years. In multivariate analysis, median time to anti-TNF initiation >1 year was the only factor associated with the risk of relapse (HR 0.58, CI95% [0.35-0.97], $p=0.036$). Among relapsers, 46 (63%) were retreated with anti-TNF. Retreatment with anti-TNF was effective in 45 (98%) patients after a median delay of 3.9 months (3.5-10.0). Infusion reaction occurred in only 2 patients.

Conclusion: In a population-based cohort of paediatric-onset IBD, the risk of relapse after anti-TNF withdrawal was high, but was not associated with major complication. Retreatment with anti-TNF was effective and well tolerated.

Contact E-Mail Address: carolina-palma@campus.ul.pt

Introduction: Patients with chronic liver disease (CLD), particularly those with cirrhosis, exhibit increased risk of developing severe illness when infected with SARS-CoV-2, primarily due to their underlying immune dysfunction and coexisting conditions. As such, vaccination plays a crucial role in safeguarding this population. Here, to fully assess the efficacy COVID-19 vaccination in patients with CLD, we thoroughly characterized the overall and SARS-CoV-2-specific cellular immune response of these patients.

Aims & Methods: Blood samples were systematically collected from patients with CLD (n=22) and healthy volunteers (n=12) at various intervals spanning one year after the initial administration of the BNT162b2 vaccine. Peripheral blood mononuclear cells (PBMCs) were isolated and stained with a panel of 22 surface markers and a viability dye, allowing for the detection of 28 immune cell subsets. In parallel, we analysed the presence of cells specific against SARS-CoV-2 peptide tetramers. Samples were analysed by flow cytometry with acquisition on a four-laser Cytex Aurora® spectral analyzer.

Results: Prior to vaccination, patients with CLD patients were already displaying fewer T cells and an increased number of B cells, comparing to healthy subjects. Within the T cell subsets, differences were significant for CD4+ T cells and the Naïve and Central Memory CD4+ subsets. At both 6-months and 1- year after vaccination, variances between groups were no longer observed. Rather, at 1-year postvaccination, T, CD8+ and CD4+ cells, as well as monocytes were found increased in both groups, suggesting that the vaccination is critical for inducing a strong cellular immune response. Analysis of SARS-CoV-2 epitope-specific cells demonstrated significantly lower frequencies of monocytes, CD4+ and CD8+ T cells, B cells, NK T cells, and NK cells including the regulatory and cytotoxic subsets recognizing the peptide tetramers in CLD patients, in comparison with healthy controls.

Conclusion: Together, these results indicate that CLD patients are capable of mounting a satisfactory immune cellular response following COVID-19 vaccination. However, the SARS-CoV-2-specific response is significantly weaker in CLD patients comparing with healthy individuals. These results reinforce the need for prioritization and/or booster vaccination for CLD patients. (Supported by 2022.08837.PTDC, FCT).

Introduction: Autoimmune hepatitis (AIH) is associated with an increased risk of developing cirrhosis and progressing to hepatic decompensation. While a successful treatment of the underlying aetiology has been shown to enable hepatic recompensation in some aetiologies of cirrhosis, implications of recompensation have not yet been assessed in decompensated cirrhosis due to AIH.

Aims & Methods: In this pilot study, we assessed the incidence and prognostic role of hepatic recompensation in patients with decompensated cirrhosis (F3/F4 histology) due to AIH (simplified AIH score ≥ 6). Patients were included at first hepatic decompensation, marked by the first occurrence of ascites, variceal bleeding or hepatic encephalopathy (HE). Patients with acute liver failure were excluded due to the indication of the high urgency liver transplantation. In accordance with the Baveno VII criteria, recompensation was defined as (i) resolution of ascites and HE despite cessation of all diuretics and anti-HE therapies, (ii) absence of variceal bleeding and (iii) sustained improvement in hepatic synthetic function (bilirubin, albumin, INR) to Child-Pugh A values. Successful aetiological control in AIH was defined as a complete biochemical response under immunosuppressive therapy, i.e., a normalisation of transaminases and immunoglobulin G.

Results: Twenty-one patients with cirrhosis due to AIH (90.5% female, age: 54.6 [39.8-61.6] years) were included at time of first decompensation (85.7% ascites, 14.3% variceal bleeding) and followed for a median of 80.4 (14.6-133.0) months. The median MELD at decompensation was 15 (11-18). Clinically, decompensation occurred in two scenarios, resulting in two distinct patient subgroups: In the first subgroup (n=10; 47.6%), patients had already been diagnosed with AIH prior to hepatic decompensation and decompensation occurred despite ongoing immunosuppressive treatment (median treatment duration: 128 [70-164] months). Decompensation in this subgroup was primarily the result of an insufficient biochemical response and none of these patients achieved hepatic recompensation. In the second subgroup, which included 11 patients (52.4%), the diagnosis of AIH was first established in the context of index decompensation. Out of these 11 patients, 5 (45.5%) did not receive immunosuppressive treatment until more than 1 month after decompensation. This delay was mainly a consequence of a delayed diagnosis and none of these patients recompensated. In contrast, in the other 6 patients (54.5%), both the diagnosis of AIH and immunosuppressive treatment were established within less than 1 month after decompensation, resulting in hepatic recompensation in 4 patients. Notably, all recompensated patients achieved a 50% decrease in transaminase levels after 4 weeks of treatment. With regard to clinical outcomes, the 4 recompensated patients survived for 62.6, 101.3, 106.3 and 202.3 months, respectively, without the need for liver transplantation. In contrast, 6 of the 17 patients who remained de-

compensated died (35.3%, all liver-related) after a median of 32.8 (15.1-58.5) months and 4 (23.5%) required liver transplantation (after median 37.5 [15.9-57.1] months).

Conclusion: In AIH patients who first present with decompensated cirrhosis, a timely diagnosis followed by a prompt initiation of immunosuppressive treatment is associated with a higher probability of recompensation and improved survival. In contrast, decompensation despite ongoing immunosuppressive therapy is associated with a poorer prognosis.

IMMUNOREGULATORY MYELOID CELLS COUNTERACT T CELL HYPERACTIVATION-INDUCED LIVER INFLAMMATION BY EXTRACELLULAR VESICLE-MEDIATED PURINE METABOLIC REGULATION

F. Yang¹, R. Men¹, J. Lin¹, J. Liu², L. Yang¹

Introduction: Dysregulated T-cell immune response-mediated inflammation is implicated in various liver diseases, yet mechanisms governing liver immune homeostasis control and therapies for limiting T-cell overactivation remain unclear. This study aims to elucidate the role of immunoregulatory myeloid cells (Mregs) in liver injury and their potential to modulate CD4⁺ T-cell hyperactivation via extracellular vesicle (EV)-mediated metabolic regulation.

Aims & Methods: Concanavalin A (ConA) mice and autoimmune hepatitis (AIH) patients were examined for alterations in purine metabolism associated with liver injury severity and therapeutic response. The expression of extracellular purine catabolism nucleases, such as CD39 and CD73, on CD11b⁺Gr-1⁺ myeloid cells (MCs) was assessed, with particular focus on liver injury conditions. The study investigated the natural expansion of the CD39⁺CD73⁺Gr-1^{high}CD11b⁺ regulatory MC (Mreg) subset during early liver injury phases and its effects on CD4⁺ T-cell hyperactivation and liver injury through in vitro and in vivo experiments. Mechanistic insights into Mreg-mediated immunosuppression were explored, particularly regarding the release of CD73^{high} EVs and their impact on extracellular AMP conversion, cAMP pathway activation, and inhibition of glycolysis and cytokine secretion in activated CD4⁺ T cells.

Results: Alterations in purine metabolism were observed in ConA mice

and AIH patients, correlating with liver injury severity and therapeutic response. CD39 and CD73 expression was markedly upregulated on CD11b⁺Gr-1⁺ myeloid cells under liver injury conditions. The CD39⁺CD73⁺Gr-1^{high}CD11b⁺ Mreg subset expanded naturally during early-stage liver injury and demonstrated efficacy in suppressing CD4⁺ T-cell hyperactivation and liver injury both in vitro and in vivo. The release of CD73^{high} EVs by Mregs facilitated extracellular AMP conversion to immunosuppressive metabolites (e.g., adenosine and inosine), activating the cAMP pathway and inhibiting glycolysis and cytokine secretion in activated CD4⁺ T cells.

Conclusion: These findings shed light on the mechanisms governing immune homeostasis during early liver injury and suggest that Mreg or Mreg-EV therapy may offer a targeted approach for preventing diverse liver diseases induced by T-cell overactivation.

Introduction: Research about sarcopenia in primary biliary cholangitis (PBC) patients is limited while sarcopenia commonly occurs in cirrhotic patients. Concomitant sarcopenia in noncirrhotic PBC patients has been rarely explored yet.

Aims & Methods: This study aimed to investigate the prevalence of sarcopenia and the associations between concomitant sarcopenia at baseline and biochemical response to UDCA treatment and clinical outcomes in noncirrhotic primary biliary cholangitis (PBC) patients.

Between January 2009 and July 2022, consecutive PBC patients were retrospectively enrolled. Sarcopenia was assessed via pretreatment CT or MRI scans at the L3 level by the skeletal muscle index. Baseline characteristics, the response rate after 6 and 12 months of ursodeoxycholic acid (UDCA) administration, liver-related adverse events and baseline CRP and IL-6 levels in liver tissue and serum were evaluated.

Results: A total of 142 noncirrhotic PBC patients were included, with sarcopenia identified in 58 (40.8%) patients. The median duration of follow-up was 5.25 (3.23, 6.50) years. The group of PBC patients with sarcopenia demonstrated a lower biochemical response rate (44.9% vs. 64.8%; P=.031) according to the Paris-II criteria after 12 months of UDCA treatment, as well as higher incidence of new-onset ascites (28.1% vs. 13.1%, P=.027) during follow-up. Higher expression levels of baseline CRP and IL-6 in liver tissue and serum were observed in PBC patients with sarcopenia (P<.05).

Conclusion: Sarcopenia was highly prevalent in noncirrhotic PBC patients. Expression levels of baseline CRP and IL-6 in liver tissue and serum were elevated in noncirrhotic PBC patients with sarcopenia. Concomitant sarcopenia at baseline may adversely affect the biochemical response to UDCA treatment and occurrence of liver-related adverse events in PBC patients without cirrhosis.

Introduction: The roles of B cells in the pathophysiology of IgG4 Related Disease (IgG4-RD) and existing clinical experience suggest that B cell depletion may be an effective therapeutic avenue. Inebilizumab is a humanized, glycoengineered CD19-directed monoclonal antibody that effectively and selectively depletes B cells. The Phase 3 MITIGATE trial (NCT04540497) is a randomized, double-blinded, placebo-controlled trial that aims to demonstrate the efficacy and safety of inebilizumab monotherapy in reducing the risk of IgG4-RD relapse.

Aims & Methods: The MITIGATE study is being conducted at 80 sites in 22 countries. The study enrolled adult IgG4-RD patients who met the ACR/EULAR Classification Criteria for IgG4-RD with a score of at least 20 as determined by an Eligibility Committee (EC). Eligibility criteria included a history of multiorgan disease and active disease at the time of screening to increase the risk of flares for the primary endpoint. Subjects were stratified based on newly diagnosed (46%) vs. recurrent (54%) disease to control for potential differences in flare risk.

The primary endpoint is time to first Adjudication Committee-determined and investigator-treated IgG4-RD flare during the 12-month randomized controlled period. The study is event-driven and is powered on the accrual of 39 disease flares, which was anticipated to require 160 subjects.

To permit evaluation of inebilizumab as monotherapy, other immunosuppressive agents are prohibited. Glucocorticoids were normalized to 20 mg/day prednisone at the time of randomization and were tapered to discontinuation at the end of study week 8.

Results: Enrolment completed in April 2023 with 135 subjects enrolled. The mean age was 58.2 years and 65% were male. Time since diagnosis ranged from 0.1 to 20.5 years (median 0.9 years). Baseline ACR/EULAR

Classification Criteria scores ranged from 20 to 74. The number of organs affected by IgG4-RD up to the time of enrolment varied from 2 to 13, with 2-3 organs affected in 41% of subjects and ≥ 6 organs affected in 24% of subjects. The pancreas, bile ducts, and liver were affected in 52%, 31%, and 7% of subjects respectively. Hepatobiliary disease was accompanied by pancreatic involvement in 95% of cases, but only 59% of those with pancreatic involvement also had hepatobiliary disease. The submandibular, lacrimal, and parotid glands, lymph nodes, kidney, sinuses, and lungs were each affected in at least 20% of the study population. These findings suggest that the study population carries substantial pancreatic and hepatobiliary disease burden and is representative of real-world IgG4-RD cohorts.

Conclusion: MITIGATE enrolled a representative IgG4-RD population in terms of both number and distribution of organs affected. More than half of participants had hepato-pancreato-biliary disease, and hepatobiliary disease without pancreatic involvement was rare. Trial results are expected in 2024 and aim to establish the safety and efficacy of CD19-targeted B cell depletion by inebilizumab in IgG4-RD, potentially leading to the first approved treatment for this disease.

THE ROLE OF TRANSIENT ELASTOGRAPHY AND ENHANCED LIVER FIBROSIS SCORE IN THE HEPATO-PANCREATO-BILIARY PHENOTYPE OF IGG4-RELATED DISEASE

S. Kaur¹, R. Motta², C. Mercer¹, E. Culver²

¹Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom, ²University of Oxford, Translational Gastroenterology and Liver Unit, Nuffield Department of Medicine, Oxford, United Kingdom

Contact E-Mail Address: rodrigo.vieiramotta@ndm.ox.ac.uk

Introduction: IgG4-related disease of the liver, pancreas, and bile ducts (IgG4-HPB) can lead to fibrosis and organ damage. Liver stiffness measurement (LSM) by vibration-controlled transient elastography and Enhanced liver fibrosis (ELF) score are validated, non-invasive methods for measuring liver fibrosis in other chronic liver diseases, but little is known about their utility in IgG4-HPB.

Aims & Methods: The aim of this study is to assess LSM using Fibroscan® and ELF in patients with IgG4-HPB. This is a retrospective observational cohort of patients meeting the ACR/EULAR classification criteria for IgG4-Related Disease at Oxford University Hospitals. Clinical data collected included demographics, organ involvement, clinical flares, serum biomarkers and organ damage. LSM was recorded in 55 IgG4-HPB patients, and sequential LSM was recorded in 32 patients. Serum ELF was

measured in 23 patients. Wilcoxon rank, Mann-Whitney U, and Fisher's exact tests were performed.

Results: Ninety-seven patients with IgG4-HPB were included; median age was 68 years $\pm$ 19, and 79% were male. Among the entire cohort, 69% had established organ dysfunction and/or damage and, when subdivided by organ involvement, damage was present in 72% of those with liver and biliary disease (IgG4-HB) and 65% of those with pancreatic disease only (IgG4-AIP) (Table 1).

	Overall cohort (n = 97)	HPB cohort (n = 57)	AIP cohort (n = 40)	p-value
Median age (IQR)	67.5 (19)	68.5 (19)	65.5 (18)	0.91
Men	77 (79%)	44 (77%)	33 (82%)	0.61
Established organ damage	67 (69%)	41 (72%)	26 (65%)	>0.99
Diabetes	33 (34%)	26 (46%)	12 (29%)	0.14
Cardiometabolic disease	41 (42%)	22 (39%)	20 (49%)	0.11
MASLD	19 (20%)	13 (23%)	6 (15%)	0.59
Mean cumulative steroid dose (SD)	7326 (17468)	9012 (21263)	4260 (3074)	0.32
Median number of flares (IQR)	1 (2)	1 (2)	0 (1)	0.25

LSM was recorded in 55 patients: IgG4-HB (n = 38) had a higher mean LSM compared with IgG4-AIP (n = 17) (6.1 kPa vs 5 kPa, p = 0.04). IgG4-HB were risk-stratified by LSM: 66% had LSM <8kPa, 21% had LSM $\geq$ 8 but <12kPa, and 13% had LSM $\geq$ 12kPa. There was a higher prevalence of metabolic associated steatotic liver disease (MASLD) and its metabolic factors (diabetes, hypertension, hypercholesterolemia, and ischaemic heart disease) in those with more advanced liver fibrosis (LSM $\geq$ 12 kPa). Furthermore, survival analysis showed that patients with LSM $\geq$ 8kPa develop organ damage faster than those with LSM < 8kPa (p=0.0086).

In longitudinal analysis, 32 patients with IgG4-HPB had serial LSMs. Of those with IgG4-HB (n = 22), 23% showed an increase in LSM over a median of 2 years (IQR 1-4). The proportion of patients meeting criteria for MASLD increased from 20% to 25% over a median of two years. In those with paired readings during active disease and remission (n = 8), there was no discernible variation in LSM.

Twenty-three patients with IgG4-HPB had an ELF test and were stratified by the score: 13/23 (56%) <9.8 and 10/23 (43%) $\geq$ 9.8. ELF accurately identified patients with more significant liver fibrosis; no patient with LSM $\geq$ 8kPa was seen in the <9.8 group (p = 0.0021). There was no association of ELF with disease activity or serum biomarkers.

Conclusion: This is the first study assessing the role of LSM by Fibroscan® and of ELF score in patients with IgG4-HPB. An increased LSM over time was associated with the accumulation of cardiometabolic risk factors, evidence of MASLD, and end-organ damage, while ELF score ruled out advanced fibrosis in this cohort concurrently.

DECODING THE ROLE OF NEUTROPHIL EXTRACELLULAR TRAPS IN AUTOIMMUNE HEPATITIS: IMPACTS ON MACROPHAGE EFFEROCYTOSIS AND MTOR PATHWAY INTERACTIONS

S. Wang¹, D. Tian¹

¹Tongji Hospital of Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China

Contact E-Mail Address: d202282081@hust.edu.cn

Introduction: Autoimmune hepatitis (AIH) is a chronic liver disease characterized by elevated immunoglobulin G (IgG), autoantibodies, and interface hepatitis. Its incidence is rising globally, while current treatments often fall short and carry significant adverse effects. In AIH, hepatocytes are prone to apoptosis from immune attacks, yet impaired clearance leads to inflammation from accumulated apoptotic cells.

Neutrophil extracellular traps (NETs) contain granule proteins, DNA, and RNA, playing a role in autoimmune responses. They can expose self-antigens, potentially worsening autoimmune reactions. NETs' role in AIH and their effect on apoptotic cell clearance require further exploration. Macrophage efferocytosis is key for immune tolerance in the liver, with disruption leading to broader inflammation and efferocytosis escape. This study investigates the impact of NETs on macrophage efferocytosis and metabolism in AIH, seeking therapeutic targets to enhance liver health.

Aims & Methods: This study aims to explore the role of NETs in the pathogenesis of AIH, elucidating the molecular mechanisms by which NETs influence efferocytosis in hepatic macrophages within the context of AIH.

Six-to-eight-week-old male C57 mice were used to create AIH models in a specific-pathogen-free (SPF) setting. Flow cytometry was used to measure changes in neutrophil levels in the liver of AIH model mice and in the peripheral blood of patients. NETs levels in serum and liver tissue were determined through ELISA and immunohistochemistry. Macrophage phagocytosis of apoptotic cells was evaluated using multiplex immunofluorescence with confocal microscopy and flow cytometry. Glycolysis levels in macrophages were assessed with a Seahorse metabolic analyzer, and transcriptomic sequencing explored underlying mechanisms, with confirmation through Western blot analysis. Histopathological changes in the liver were examined with hematoxylin and eosin (H&E) staining, while Sirius Red staining assessed fibrosis. Serum levels of alanine transaminase and aspartate transaminase were used to gauge liver damage.

Results: Autoimmune hepatitis (AIH) features a reduced efferocytosis index in the liver, with fewer macrophages conducting efferocytosis and increased apoptotic cells. AIH mouse models reveal a significant rise in liver neutrophils, while AIH patients show an accumulation of neutrophil extracellular traps (NETs) in their livers and peripheral blood. Macrophages pretreated with NETs exhibit decreased phagocytosis of apoptotic cells. When DNase I clears NETs in AIH mice, liver inflammation and fibrosis are reduced, and apoptotic cells decrease. A comparison between AIH model mice with and without NETs clearance demonstrates a significant increase in efferocytosis by macrophages, while unengulfed apoptotic cells decline. Glycolysis in macrophages is significantly inhibited after NETs intervention, with the mTOR pathway showing downregulation, confirmed by Western blot analysis. However, when macrophages are pretreated with an mTOR-specific agonist, glycolysis levels and efferocytosis are restored compared to controls.

Conclusion: In AIH, increased levels of NETs or their components in the liver bind to TLR8 receptors, leading to downregulation of the mTOR pathway in hepatic macrophages. This interaction triggers metabolic reprogramming, inhibiting glycolysis and affecting cytoskeletal integrity. The resulting suppression of efferocytosis leads to an abnormal accumulation of apoptotic cells, which contributes to AIH progression.

Disclosure: Nothing to disclose.

CD177⁺ NEUTROPHILS EXERT PROTECTIVE EFFECT IN EXPERIMENTAL AUTOIMMUNE HEPATITIS

Y. Shen¹, T. Jia¹, C. Huang¹, M. Shen¹, X. Fan¹, R. Men¹, L. Yang¹

Introduction: Neutrophils could be recruited into liver in autoimmune hepatitis (AIH) and experimental AIH (Concanavalin A induced hepatitis), but the role of neutrophils in these kinds of immune related hepatitis has rare research to clarify. As previous reports, CD177 expressed exclusively on neutrophils, CD177⁺ neutrophils could alleviate inflammation in inflammatory bowel disease, and it could produce neutrophil extracellular traps that promote biliary atresia. However, there is no report about CD177⁺ neutrophils involved in AIH or experimental AIH.

Aims & Methods: In this study, we wanted to explore to role of neutrophils in AIH and wondered whether CD177⁺ neutrophils exert protective effect in it. We collected clinical samples of AIH patients and healthy control (HC), and established experimental AIH animal model by using Concanavalin A (ConA). Anti-Ly6G antibody was used as pretreatment to depleting neutrophils before ConA injection. Wild type (WT) and CD177 knock out (KO) C57BL/6J female mouse were used to construct different experimental AIH model. Flow cytometry analysis was used to detect the percentage of neutrophils in blood and liver. Detected serum biochemical indicators (ALT: alanine aminotransferase, AST: aspartate aminotransferase) and performed staining in liver tissues to evaluate liver injury.

Results: For AIH patients, CD177⁺ neutrophils in peripheral blood were significantly increased ($P < 0.05$). And for immunohistochemistry (IHC), the positive areas of CD66b (a surface marker of neutrophils) and CD177 were more obvious in liver tissues of AIH patients ($P < 0.05$). For animal experiment, we successfully established model of experimental AIH. In this model, liver injury was significant in ConA group than in normal control (NC) group, which showed prominent liver necrosis in hematoxylin-eosin (HE) staining and higher serum ALT and AST ($P < 0.05$). Positive IHC areas of Ly6G and CD177 were more obvious in liver tissues of ConA group, which meant the increased infiltration of neutrophils. We found that distributions of neutrophils were different in different organ. Compared to NC group, the amount of neutrophils in ConA group was decreased in bone marrow and increased in peripheral blood and liver, and its increase in liver trended to be more obvious ($P = 0.096$). So, we speculated that neutrophils mainly migrated to liver from marrow in ConA model. After depleting neutrophils, we through flow cytometry analysis to verify the depletion of neutrophils (CD11b⁺ Ly6G⁺ cells) in anti Ly6G-ConA group was thorough. HE staining showed liver injury appearances in ConA group and Ly6G isotype-ConA group were more severe than that in normal saline (NS) group and in anti Ly6G-ConA group. Similarly, ConA group and Ly6G isotype-ConA group had higher levels of serum ALT and AST than the other two groups. Finally, we used CD177 KO mouse to determine the role of CD177⁺ neutrophils in ConA model. HE staining showed the area of liver necrosis in CD177 KO-ConA group was largest. As for liver function, CD177 KO-ConA group also had the highest levels of serum ALT and AST ($P < 0.05$), which improve that the liver injury in this group was the most severe.

Conclusion: Neutrophils involved in AIH and experimental AIH. In experimental AIH, depletion of neutrophils could alleviate liver injury, and CD177⁺ neutrophils could exert protective effect in it.

Disclosure: Nothing to disclose.

Introduction: Bone loss is a frequently observed complication in patients with autoimmune liver diseases (AILD). The exact risk of osteopenia and osteoporosis is unclear. Risk factors of bone loss require clarification. DEXA is both the screening method and the treatment guide. According to the EASL CPG currently in force, DEXA should be performed for all AILD patients at presentation and during follow-up visits. The outline standard is 80% assessment within 5 yrs.

Aims & Methods: Since 2017, the University of Debrecen (UNIDEB) prospectively collected data of AILD patients. In 2019, UNIDEB joined the prospective, multicenter, quality-controlled R-LIVER Registry on rare liver diseases launched by The European Reference Network for Hepatological Diseases (ERN RARE-LIVER). A total of 209 prospective AILD patients were included. Clinical, laboratory, imaging, and DEXA data were collected at the time of diagnosis and during yearly follow-up visits. A retrospective AILD patient cohort (n=176, 2010-2016) was used as a control group for monitoring guideline-adherence and clinical care standards of bone loss. We aimed to 1) assess bone loss at the time of diagnosis during the follow-up; 2) define risk factors of bone loss; 3) evaluate the accomplishment of quality objectives for the diagnosis of bone loss and analyze how the R-LIVER Registry supported quality improvement in the local level.

Results: According to DEXA results, 55.7% of patients had some degree of bone loss and 24.5% had osteoporosis at the time of diagnosis with the highest prevalences detected in PBC (67.5% and 32.5%, respectively). Older age (OR:1.050), post-menopausal status (OR:4.821), presence of significant liver fibrosis ($>9.2\text{kPa}$; OR:3.966, $p < 0.01$ for all) and elevated γGT levels (OR:1.001; $p = 0.041$) were risk factors for osteoporosis at diagnosis in the pooled patient group. mHAI was a risk factor in AIH, but degree of cholestasis was not in PSC and PBC separately. 171 patients had at least 1 year follow-up and 56 of them had repeated DEXA. Significantly more patients had DEXA assessment in line with the EASL CPG after joining ERN RARE-LIVER compared to the previous period. DEXA at diagnosis improved from 8.5% (retro) to 23.7% (2017-2018) then to 66% (all ERN), reaching 73.7% in 2023. In patients who had DEXA at diagnosis, guideline adherence of DEXA follow-up steadily improved from 42.9% (2017-2018) to 56.3% (2019-2020) and 88.6% (2021-2022). The outline standard was not achieved prior accession (17% had DEXA in 5 yrs retro and 50.8% between 2017-2018), but thereafter DEXA assessment was 72.7% after only 2 yrs of median follow-up (IQR: 0.75-4.1).

Conclusion: Bone loss was a frequent complication in our prospective AILD patient cohort. We identified several general and liver disease related risk factors, which warrant validation in the whole ERN cohort. After joining ERN RARE-LIVER program, gradual and significant improve-

ment was observed in the diagnosis of bone loss in AILD that verifies quality-controlled prospective registries as important tools for implementation of complex care in the clinical practice at local level.

Disclosure: Nothing to disclose.

Patient outcome: Pancreas

“ENHANCING SURVIVAL WITH PRECISION: EFFICACY AND SAFETY OF ENDOSCOPIC ULTRASOUND-GUIDED RADIOFREQUENCY ABLATION IN UNRESECTABLE PANCREATIC ADENOCARCINOMA – A PROSPECTIVE ANALYSIS”

M.F. Castro¹, J. Vargas¹, A. Ochoa Palominos²

¹*Caja Costarricense del Seguro Social, Hospital San Juan De Dios, San Jose, Costa Rica*, ²*Hospital Calderón Guardia, San José Costa Rica, Gastroenterology, Escazú, Costa Rica*

Contact E-Mail Address: mfcastr@ccss.sa.cr

Introduction: Endoscopic ultrasound-guided radiofrequency ablation (EUS-RFA) has emerged as a promising minimally invasive technique for the management of unresectable pancreatic adenocarcinoma. Despite its potential, the practical outcomes and overall survival implications of this technique require thorough assessment in real-world settings.

Aims & Methods: This prospective study aimed to evaluate the feasibility, safety, and efficacy of EUS-RFA in patients with locally advanced or metastatic pancreatic adenocarcinoma. For the procedure, an RFA 19-g needle with an electrode active tip length of 10 mm was introduced into the tumor through the working channel of the echoendoscope. The generator settings were set at 35 W, and energy was applied from the distal to the proximal margin of the tumor until the entire lesion was treated. (video 1 EUS RFA PADC.mp4) The primary endpoints were technical success, complication rate, and overall survival.

Results: Twenty consecutive patients (58% female; average age 60 +/- 11.5 years; average tumor diameter, 37 +/- 16.7 mm) underwent EUS-RFA combined with subsequent chemotherapy. Sixteen patients (80%) were diagnosed with locally advanced adenocarcinoma, while four (20%) had metastatic disease. Technical success was achieved in 100% of the cases. The median overall survival was 15 +/- 2.2 months. No adverse events were reported. It should be noted that a patient with locally advanced adenocarcinoma downstaged after multimodal therapy and underwent surgical resection.

Conclusion: EUS-RFA is a feasible and safe treatment modality for patients with unresectable pancreatic adenocarcinoma, with high technical success and low complication rates. Future studies with larger cohorts are needed to confirm these findings and optimize treatment protocols.

HEPATOPANCREATODUODENECTOMY FOR EXTRAHEPATIC CHOLANGIOCARCINOMA -A SERIES OF 100 CONSECUTIVE CASES FROM AN EXPERT CENTER IN JAPAN-

T. Sugiura¹

¹*Shizuoka Cancer Center, Division of Hepato-Biliary-Pancreatic Surgery, Sunto-Nagaizumi, Japan*

Contact E-Mail Address: t.sugiura@scchr.jp

Introduction: Hepatopancreatoduodenectomy (HPD) is indicated for widely spreading cholangiocarcinomas. However, the procedure remains controversial due to high morbidity and mortality, as well as uncertain oncological benefits.

Aims & Methods: The aim of this study is to evaluate the efficacy and safety of HPD for extrahepatic cholangiocarcinoma. A total of 100 patients who underwent HPD between 2003 and 2020 were reviewed. Short- and long-term outcomes were compared with those of patients who under-

went hepatectomy with extrahepatic bile duct resection (HT-B) (n=203) and pancreatoduodenectomy (PD) (n=209) for extrahepatic cholangiocarcinoma during the same period.

Results: The median operating time and blood loss of HPD were 668 min and 1842 mL, which were significantly longer and greater in comparison to the HT-B (552 min and 1264 mL) and PD (457 min and 911 mL) groups. The rate of clinically relevant postoperative complications (Clavien-Dindo grade ≥ 3) after HPD was 82%, which was significantly greater in comparison to the HT-B (39%) and PD (68%) groups. However, the mortality rate was 2% and was almost comparable to the HT-B (2.5%) and PD (1.4%) groups. The 3- and 5-year survival rate, and median survival time were 59.0%, 40.7%, and 50 months, respectively, in the HPD group; 61.1%, 41.8%, and 45 months in the HT-B group; and 60.7%, 45.4%, and 48 months in the PD group. No significant differences were observed between the groups. Thirty-six patients who underwent HPD survived for 5-years.

Conclusion: Although HPD is technically demanding and forces stress on patients, it can be performed with acceptable mortality and survival rate. HPD for widely spreading cholangiocarcinoma should be considered a standard procedure in expert hepato-pancreato-biliary centers.

MEASURING INEQUALITY AND SPATIAL DISTRIBUTION OF CHRONIC LIVER DISEASE MORTALITY IN EUROPE FROM 2013 TO 2018 USING DATASET LINKAGE OF ROUTINELY COLLECTED NOMENCLATURE OF TERRITORIAL UNITS FOR STATISTICS (NUTS) 2 REGIONAL LEVEL DATA

E. Meehan¹, J. Enticott²

²Monash University, Monash Centre for Health Research and Implementation, Melbourne, Australia

Contact E-Mail Address: ejmeehan@gmail.com

Introduction: Health disparities in the burden of chronic liver disease (CLD) exist across socioeconomic, geographic, and ethnic lines.¹ However, the extent and nature of disparities in European patients with CLD has been minimally explored.

Aims & Methods: This study aims to evaluate socioeconomic and geographic disparities in CLD mortality across Europe between 2013 and 2018. We analysed 6 years of standardized death rates for CLD in NUTS 2 regions within current European Union (EU) member states. NUTS 2 regions are subnational areas containing between 800,000 and 3,000,000 inhabitants, used for standardizing cross-border comparisons.² We linked Eurostat datasets of 'Gross Domestic Product (GDP) Purchasing Power Standards (PPS) per inhabitant' and 'Causes of death'. Standardized death rates were weighted against the European Standard Population, and CLD mortality was defined using the codes K70, K73, and K74 from the International Classification of Diseases, 10th Revision. We chose a start date of 2013 as it coincided with Croatia's accession into the EU and the first reporting of CLD mortality in several regions. We chose an end date of 2018 due to significant missing data in subsequent years. Regions were divided into quintiles from most to least disadvantaged based on GDP PPS per inhabitant, and summary statistics were calculated for each quintile. Concentration indices and curves were generated in Stata, using GDP PPS per inhabitant to rank regions by socioeconomic status. Finally, choropleth maps were generated to visually compare CLD mortality across NUTS

2 regions. We adhered to REporting of studies Conducted using Observational Routinely-collected health Data (RECORD) statement guidelines.³

Results: Of the 242 NUTS 2 regions in current EU member states, GDP data was complete for all regions, but CLD mortality data was unavailable in 3 Croatian regions in all years and 1 French region in 2013. 238 (98.4%) regions were therefore analysed in 2013, and 239 (98.8%) were analysed in all other years. In 2013, median GDP PPS per inhabitant was \$23,550 (IQR: \$17,600 to \$30,000), and median standardized death rate across all regions was 12.94 per 100,000 (IQR: 8.46 to 17.64). The rate in the most disadvantaged quintile was 1.38 times higher than this, at 17.9, and 1.43 times higher than the rate in the least disadvantaged quintile (12.52). Concentration indices and curves indicated that the burden of CLD mortality was concentrated in regions with lower GDP PPS per inhabitant. Indices ranged from -0.11 to -0.13, with $p < 0.001$ in all years indicating significant inequality. Choropleth maps showed higher death rates in Eastern and Central Europe. The top 6 regions by CLD mortality were all located in Romania. The highest in all years was the Sud-Est region, where the rate ranged from 59 to 64 deaths per 100,000.

Conclusion: We identified socioeconomic disparities in the distribution of CLD mortality and found a high burden of disease in Eastern European nations. The concentration of mortality in the poorest quintile, with a death rate 1.38 times higher than the overall population, is similar to findings in Australia, where the poorest quintile's death rate is 1.42 times higher than the population at large.⁴ Limitations included a retrospective design and a lack of granular data on sub-classifications of CLD and potential confounders such as rural status. Ultimately, our findings identify potential targets for health promotion and contribute to an understanding of how disadvantage contributes to health disparities in CLD.

COMPARING PLASTIC VS BIODEGRADABLE PANCREATIC STENTS FOR THE PREVENTION OF POST-ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY PANCREATITIS: PRELIMINARY RESULTS OF A SINGLE-CENTER RANDOMIZED CONTROLLED TRIAL

C. Robles-Medrandá¹, D. Cunto¹, M. Egas-Izquierdo¹, M. Puga-Tejada¹, R. Del Valle¹, J. Baquerizo-Burgos¹, M. Arevalo-Mora^{1,2}, H. Alvarado-Escobar¹, H. Pitanga-Lukashok¹, J. Alcivar-Vasquez¹

Contact E-Mail Address: miguel.puga01@hotmail.com

Introduction: Endoscopic retrograde cholangiopancreatography (ERCP) stands as the primary choice for treating pancreatobiliary disorders. Among its complications, post-ERCP pancreatitis (PEP) is the most frequent, with a prevalence ranging from 4-10%, and reaching up to 15% in high-risk patients. To mitigate the hydrostatic pressure contributing to PEP in high-risk patients, the insertion of a pancreatic duct stent is considered a preventive measure. The available options for pancreatic duct stenting include plastic pancreatic stents (PPS) and biodegradable stents (BDS) placement; However, currently, there is no available data on their efficacy, nor the best setting for choosing between the two.

Aims & Methods: Our aim is to compare the effectiveness of PPS vs BDS for the preventing PEP. A single-center, prospective, randomized controlled trial (RCT) in patients with biliary tract disease requiring ERCP was conducted from January/2022 to June/2023. Subjects ≥ 18 years-old, with a non-manipulated pancreatic papilla and written informed consent were included in the study. Patients not requiring or failed stenting, hemodynamically unstable, pregnant or nursing subjects, at risk of fluid overload, cholangitis, sepsis, acute/flare-up chronic pancreatitis, recent biliary tract manipulation, uncontrolled coagulopathy, kidney or liver failure or comorbidities impacting the cardiac-risk assessment were excluded. During ERCP, PPS (5F $\times$ 4cm) or BDS (6F $\times$ 4cm or 6F $\times$ 6cm) were randomly selected and placed. At three-days and five-weeks post-procedure, the patients required follow-up assessment to rule-out PEP based on physical examination findings, laboratory tests (amylase, lipase, PCR, WBC and total bilirubin), abdominal ultrasound, and history of any post-ERCP hospitalization.

Results: Ninety-seven patients were enrolled (54 BDS and 43 PPS), with a median age of 53 years, 63.9% females. The main indication for ERCP was choledocholithiasis (89.7%). The median time for biliary cannulation was 5 minutes, requiring sphincterotomies in 90/97 patients. Additionally, from the 43/97 PPS cohort, biliary stents simultaneous placement was required in 13/43 (30.2%), compared to 4/54 from BDS cohort (7.4%; $p=.0076$). It was shown that median post-ERCP total bilirubin was significantly lower in both PPS (1.04 vs 0.96; $p=.0338$) and BDS cohort (1.04 vs 0.52 mg/dL; $p=.0044$). The same was observed for median C-reactive protein in PPS (7.03 vs 4.10 mg/dL; $p=.0338$) and BDS (11.2 vs 5.1 mg/dL; $p=.01$). Meanwhile, median post-ERCP lipase was significantly higher in both PPS (47 vs 54.8 mg/dL; $p=.05$) and BDS (48.5 vs 110 mg/dL; $p=.0134$). PEP was noticed in 8/97 (8.2%), with no significant difference in prevention when PPS and BDS were compared (14% vs 3.7%; $p=.133$).

Conclusion: A lower but non-significant rate of PEP prevention using BDS vs PPS was noticed. The significant reduction on total bilirubin levels, mainly in the BDS cohort, deserves further studies that must be conceived around this endpoint.

TIME TO SURGERY DOES NOT AFFECT THE SURVIVAL OUTCOME IN PATIENTS WITH PERIHILAR CHOLANGIOCARCINOMA

Y. Tohmatsu¹, K. Ohgi¹, R. Ashida¹, M. Yamada¹, S. Otsuka¹, Y. Kato¹, K. Uesaka¹, T. Sugiura¹

¹Shizuoka Cancer Center Hepato-Biliary-Pancreatic Surgery, Division of Hepato-Biliary-Pancreatic Surgery, Sunto-Nagaizumi, Japan

Contact E-Mail Address: y.tohmatsu@scchr.jp

Introduction: Patients with perihilar cholangiocarcinoma (PHC) often require lengthy preoperative management, resulting in a long time to surgery (TTS). However, the relationship between the TTS length and postoperative survival outcome remains unknown.

Aims & Methods: This retrospective single-center study included 224 patients with PHC (2011–2020). TTS was defined as the period from the date of the diagnosis by computed tomography to the date of surgery; the median TTS was 64 (range, 19–212) days. The patients were divided into 2 groups with a TTS cutoff value of 64 days. The surgical and oncological outcomes were then compared between the long- (n=116) and short-TTS (n=108) groups.

Results: Radical resection rate was 74% in long-TTS group and 84% in short-TTS group. The frequencies of preoperative biliary infection (52% vs. 33%, $P=0.004$) and portal vein embolization (84% vs. 49%, $P<0.001$) were significantly higher in the long-TTS group than in the short-TTS group. There was no marked difference in the postoperative mortality rate (2% vs. 3%, $P=0.697$) and histopathological findings, such as lymph node metastasis (41% vs. 43%, $P=0.871$) and R1 resection rate (15% vs. 9%, $P=0.193$), between the groups. The overall survival was comparable between the groups (median survival time, 47 vs. 43 months, $P=0.627$). In the multivariate analysis, only lymph node metastasis was an independent prognostic factor (hazard ratio, 1.494; $P=0.044$), although TTS was not associated with the survival.

Conclusion: TTS did not affect the survival outcomes of patients who underwent surgical resection for PHC. It is essential to achieve radical resection safely with appropriate preoperative management, regardless of the length of TTS.

Disclosure: Nothing to disclose.

BREAKING BOUNDARIES: SCARLESS CHOLECYSTECTOMY ACHIEVED WITH A NOVEL FLEXIBLE ENDOSCOPIC ROBOTIC PLATFORM

S. Perretta^{1,2}, G. Carlino^{3,1}, J. Marescaux¹

¹IRCAD, University of Strasbourg, Institute for Research on Cancers of the Digestive Tract, Strasbourg Cedex, France, ²IRCAD-IHU, Surgery, Strasbourg, France, ³Policlinico Universitario Agostino Gemelli, Università Cattolica Del Sacro Cuore, Surgical Digestive Endoscopy, 00168, Italy

Contact E-Mail Address: silvana.perretta@ircad.fr

Introduction: While robotic surgery has enhanced the precision of laparoscopy, its rigid instrumentation presents limitations. Flexible endoscopic instruments offer potential advantages in reach and access, yet have historically lacked the stability and force needed for human application. The advent of a flexible robotic platform holds promise in providing the necessary visualization, stability, and instrumentation for safe and effective procedures in humans. This video demonstrates the proof of concept for cholecystectomy using a novel flexible robotic platform.

Aims & Methods: In a porcine in-vivo model, a flexible robotic platform was used to perform a cholecystectomy. The platform is a master-slave system with a physician console, patient cart, an 18mm wide, 45cm long flexible shaft, and two 6mm robotic effector arms with 7 degrees of freedom. A 2cm incision was made at the level of the umbilicus to introduce the platform. Once in position, an atraumatic grasper and scissors were introduced under endoscopic control of the cobra camera. Cholecystectomy was performed in a hybrid format, using flexible instruments with one additional 5mm laparoscopic grasper to optimize exposure of the operating field. The triangle of Calot and gallbladder were successfully dissected, and the cystic duct and artery were clipped and divided with the flexible endoscopic instruments. A 5mm laparoscopic camera was used to enhance lighting in the peritoneal cavity beyond the cholecystectomy site, facilitating comprehensive monitoring of the entire procedure and platform in action.

Results: Total operative time was 22 minutes. There were no intraoperative complications. Cholecystectomy was performed safely and completely with the flexible endoscopic instruments.

Conclusion: Single incision cholecystectomy with this novel flexible robotic platform is safe and feasible. The approach may combine the best technical aspects of laparoscopic, robotic, and endoscopic surgery, minimizing trauma and external scars although improvement in exposure and lighting are desirable. Clinical investigation with this promising technology is ongoing.

SUSTAINABLE SURGERY - QUANTIFYING THE CARBON FOOTPRINT OF A LAPAROSCOPIC CHOLECYSTECTOMY: A LIFE-CYCLE ASSESSMENT STUDY (CO₂SURG-STUDY)

S. Bluiminck¹, D.J. Comes¹, E. Kooistra², L. De Nes³, F. Van Workum⁴, H. Touw², M.M. Eussen⁵, N.D. Bouvy⁵, T. Stoberneck², P.R. De Reuver¹

Contact E-Mail Address: stijn.bluiminck1@radboudumc.nl

Introduction: The Dutch healthcare sector is responsible for over 7% of the national carbon footprint and 4% of all produced waste, with a substantial contribution of the surgical community. (1-2) Numerous sustainability initiatives have emerged, each targeting specific aspects of surgical procedures such as utilization of disposables, waste management, and use of inhalation anaesthesia.

However, for the surgical team to gain insights into the environmental impact of procedures and to identify the primary contributors guiding mitigation strategies, a comprehensive assessment of the surgical procedures is imperative.

This study aimed to assess the carbon footprint of laparoscopic cholecystectomy (LC) and identify mitigation options by performing a life-cycle assessment (LCA).

Aims & Methods: A multicentre observation study of 15 elective LCs was conducted in 3 hospitals. This LCA studied the entire life cycle of processes and materials involved in the surgical procedure including all surgical instruments (i.e., reusable, and disposable instruments), medication (including anaesthesia), sterilisation process of reusable equipment, energy consumption, operating room (OR) scrubs and linen, and travel movements of operating room personnel and patients. The primary outcome measure was the carbon footprint in kg CO₂ equivalents (eq.) of the operation. Secondary outcomes were identifying major contributing factors and mitigation options. Based on feasible mitigation measures, the carbon footprint of a best-case scenario was determined. The LCA was performed according to ISO14040 guidelines and ReCiPe 2016 methodology. (3-4)

Results: The carbon footprint of a LC was 56.5 kg CO₂ eq. The main contributors were disposable materials, accounting for 40% of the total carbon footprint (22.7 kg CO₂ eq. IQR 21.5-24.6), energy consumption (11%, 6.1 kg CO₂ eq.; IQR 5.4-7.9), and transport of personnel (13%, 7.1 kg CO₂ eq.; IQR 5.5-9.6). Reusable products made up 22% (12.5 kg CO₂ eq.; IQR: 12.5-12.5) with 81% attributable to the sterilisation process. Medication made up 3.0 kg CO₂ eq. (5%, IQR: 0.08-5.9), with inhalation anaesthetic, sevoflurane responsible for 96% of the carbon footprint. The Best-case scenario included transitioning to reusable instruments, reducing surgical drapes, adopting total intravenous anaesthesia, and switching to 100% green energy, reducing the total footprint by 23%.

Conclusion: This study showed the carbon footprint of a LC and provided insights in the most important contributing factors. A substantial reduction in the carbon footprint can be achieved by replacing disposable surgical instruments (trocars and clipper) with reusable alternatives, reducing surgical drapes, switching to total intravenous anaesthesia, and transitioning to 100% green energy. The results of this study extend beyond LC and can be used to accelerate and provide guidance for sustainability initiatives, an essential step towards sustainable surgical care.

Moreover, the most impactful approach to reduce the carbon footprint lies in avoiding unnecessary procedures. Recent studies have shown that a restrictive or conservative strategy for uncomplicated gallstone disease is comparable to cholecystectomy as a treatment option in terms of quality of life and biliary-related complications (5-6). Therefore, we are currently conducting a carbon footprint effectiveness analysis in the United Kingdom and the Netherlands to determine the carbon footprint reduction potential of a conservative or restrictive strategy for uncomplicated gallstone disease. We anticipate being able to present the results at the congress.

Introduction: Difficult pancreatic duct stones, including large and/or impacted pancreatic duct stones, cannot usually be treated by conventional endoscopic retrograde cholangiopancreatography (ERCP). Extracorporeal shock wave lithotripsy (ESWL) and surgery including Frey operation are the main treatment for such difficult pancreatic duct stones. Recently, cholangiopancreatography-assisted lithotripsy using electrohydraulic lithotripsy (EHL) or laser lithotripsy (LL) provides an alternative modality for ductal clearance.

Aims & Methods: We aimed to evaluate the clinical outcomes of cholangiopancreatography-assisted lithotripsy and Frey surgery in patients with difficult pancreatic duct stones.

From January, 2018 to December, 2023, a total of 12 (10 male and 2 female) consecutive patients, 51 (38-71) years old, with large and/or impacted pancreatic duct stones undergoing single-operator cholangiopancreatography-assisted lithotripsy using EHL and/or LL, and 14 (10 male and 2

female) consecutive patients, 48 (33-62) years old, undergoing Frey surgery in a medical center were retrospectively analyzed. Clinical outcomes including stone size, lithotripsy and surgery procedures, ductal clearance, complications, and length of hospital stay were evaluated.

Results: In the group of cholangiopancreatography-assisted lithotripsy, 11 (91.7%; 11/12) patients were successfully treated in 19 (median 2; range 1-3) sessions including LL (n=16) and EHL (n=3) to achieve ductal clearance (Clinical success). The technical success rate was 94.7% (18/19). Six (50%; 6/12) patients with pancreatic duct stones were successfully treated at the first session of cholangiopancreatography-assisted lithotripsy. After the procedure, mild pancreatitis occurred in 5 (26.3%; 5/19) patients. The median length of hospital stay was 4 (2-9) days. In the group of Frey surgery, 11 (78.6%; 11/14) patients underwent the surgery successfully. Adverse events after Frey surgery occurred in 3 (21.3%; 3/11) patients, including intra-abdominal abscess, peritonitis and bacteremia, respectively. The median length of hospital stay was 16 (7-58) days.

Conclusion: Cholangiopancreatography-assisted lithotripsy is an effective and safe modality for difficult pancreatic duct stones. Comparing with Frey surgery, cholangiopancreatography-assisted lithotripsy can be an initial therapy.

Disclosure: The authors declare no conflicts of interest.

Introduction: Diagnosis of chronic pancreatitis (CP) is challenging, especially in early stages when typical clinical signs and parenchymal changes are lacking. To date, evaluation by endoscopic ultrasound (EUS) using Rosemont criteria (RC) is the gold standard for the diagnosis of CP, but represents an invasive method with still suboptimal accuracy. Therefore, it is of crucial interest to develop non invasive, widely applicable tests for the diagnosis of CP. Recently the Gemelli chronic pancreatitis ultrasound score (USCP) has been developed to fill this gap (1). Comparable to liver stiffness measurement, transabdominal ultrasound (US) with 2D shear wave elastography (2D SWE) could represent an additional alternative for the diagnosis of CP. It uses measurement of tissue stiffness, which increases naturally with chronic inflammatory changes, present in CP (2).

Aims & Methods: We conducted a single center prospective case control study where all the included subjects underwent EUS first (for the suspicious of CP or other reasons such as lithiasis), with RC defined patient cohorts with chronic pancreatitis or absence of parenchymal changes. Patients with and without CP subsequently underwent US with evaluation of the pancreas using 2D SWE (in m/s) and characterization by the USCP score (LogiqE10, GE Healthcare). Primary outcome was agreement

between the different evaluation techniques, namely RC and 2D SWE. Secondary outcome was the evaluation of a cut off value of SWE differentiating values in CP from normal values. Main exclusion criteria were patients with liver cirrhosis, acute pancreatitis and inability to visualize the pancreas with US.

Results: 51 patients with CP and 51 without CP were included. Median SWE were statistically different between groups (no CP 1.50m/s; IQR 1.34-1.63 and with CP 1.83 m/s; IQR 1.68-2.08; $p<0.0001$). Patients with RC indeterminate for CP had lower SWE values compared to patients with RC consistent with CP (Median 1.67m/s, IQR 1.52-1.72 vs. 1.90 m/s, IQR 1.72-2.12, $p<0.0001$). Median USCP Score significantly differed between groups (no CP 0-1 points, with CP 3-9 points, $p<0.0001$). SWE values did not correlate with age, BMI, HbA1c or stool elastase levels, but correlated significantly with USCP score ($p<0.001$) and RC ($p<0.001$). USCP Score significantly correlated with BMI ($p=0.011$), stool elastase levels ($p<0.001$), HbA1c ($p=0.002$) as well as RC ($p<0.0001$). We defined a cutoff- SWE value of <1.42 m/s to rule out CP with a sensitivity of 97% (NPV 98%) and a SWE cut off >1.97 ms/s to diagnose CP with a specificity of 97% (PPV 92%).

Conclusion: Transabdominal ultrasound evaluation of the pancreas with 2D SWE is a promising, widely applicable and non-invasive tool for the diagnosis of CP. More studies with larger cohorts confirming the results are necessary.

SCREENING FOR GASTRIC CANCER IN PORTUGAL: A MULTICENTER CROSS-SECTIONAL STUDY IN PRIMARY HEALTHCARE

P. Pimentel-Nunes¹, R.P. Bastos¹, T. Moreira¹, M. Coelho-Rocha¹, R.F. Veloso¹, D. Libânio¹, C. Bernardes¹, T. Pinto-Pais¹, M. Bento-Miranda¹, F. Barreto¹, L. Prado¹, A. Maia-Gonçalves¹, L. Rafael¹, R. Panzeri-Rodrigues¹

¹Unilabs Portugal, Porto, Portugal

Contact E-Mail Address: pedronunesml@gmail.com

Introduction: Gastric cancer screening is not formally recommended in Portugal, despite having an incidence rate of 26/100,000 inhabitants, which contrasts with recommendations from other countries with moderate incidence.

Aims & Methods: Aims: To assess the frequency of screening indications and correspondent diagnoses in patients referred for upper endoscopy from primary healthcare.

Methods: A multicenter cross-sectional study including patients who underwent upper endoscopy at 13 national endoscopy units from January to March 2024.

Results: 6320 patients were included (57% male, mean age 58). Cancer screening was the indication for upper endoscopy in 1775 patients (28% of total; 52% male, mean age 60). Biopsies of the antrum and corpus were performed in 91% of those exams, and virtual chromoendoscopy was used in 19% of screening endoscopies (vs 34% for atrophic gastritis surveillance, $p<0.05$). Endoscopic staging for intestinal metaplasia was performed in 13%. By regions, screening indication was more common in Minho (35%) and less in the Lisbon region (15%, $p<0.05$ vs other regions). Only 21% of exams were considered normal, with the main findings being: erythematous gastritis (31%); atrophic gastritis (16%, 1% autoimmune gastritis), reflux esophagitis (15%), papular gastritis (10%), erosive gastritis (8%), gastric polyps (5%), erosive duodenitis (3%), peptic ulcers (3%), subepithelial lesions (1.5%) and Barrett's esophagus (0.5%). Histologically, 30% of patients had intestinal metaplasia, 5% in both the antrum and corpus. Fourteen neoplastic lesions (0.8%) were identified: 5 gastric neoplasms (0.3%), 4 superficial gastric lesions (0.2%), 2 esophagus/junction neoplasms (0.1%), 2 superficial junction lesions (0.2%), and 1 ampulloma (0.1%). Ten percent of patients would require future endoscopic surveillance.

Conclusion: A significant proportion of upper endoscopies in Portugal are already performed for cancer screening, which seems justifiable given the high proportion of clinically relevant alterations identified. The low proportion of exams with chromoendoscopy suggests that measures are needed to increase the use of this technique in clinical practice.

Disclosure: Nothing to disclose.

Introduction: The risk of gastric cancer is expected to decrease with reduced *Helicobacter pylori* (*H. pylori*) infection rate. Although periodic endoscopic screening for gastric cancer is widely performed in East Asia, the optimal screening strategy remains unclear. Cost-effectiveness analysis (CEA) is an effective method to objectively compare different screening methods. However, no studies have compared the cost-effectiveness of endoscopy-based screening strategies.

Aims & Methods: This study aimed to determine the most cost-effective endoscopic screening strategy for the detection and treatment of gastric cancer in a modern Japanese cohort.

This study consisted of two phases: clinical data collection and analysis, followed by simulation model development. The following data was retrospectively extracted from participants who received screening endoscopy between April 2019 and March 2023: age, *H. pylori* infection status, presence of intestinal metaplasia, pathological diagnosis of gastric cancer, and the interval between the most recent endoscopies. A Markov state transition model was constructed based on the cohort data.

In this model, the prevalence of *H. pylori* infection and intestinal metaplasia, the transition probabilities between each state, and the probabilities of incidence of gastric cancer and treatment were defined. In the base-case analysis, the cost-effectiveness of 15 strategies with different starting ages (40/50/60 years) and screening intervals (1/2/3/4/5 years) was compared.

The net monetary benefit (NMB) and incremental cost-effectiveness ratio (ICER) of quality-adjusted life-years (QALY) gained by treatment were used as outcomes. The NMB is a measure of the difference between the cost required for a strategy and the cost threshold for the same effect; the larger the NMB of a strategy, the more cost-effective it is. In contrast, a lower ICER is considered more cost-effective.

	Dominance	Cost (JPY/USD)	Incremental Cost (JPY/USD)	Effectiveness (QALY)	Incremental effectiveness (QALY)	ICER (JPY/USD) /QALY	NMB (JPY/USD)
Every 4-year screening strategy (50 years old)	Reference	116,960 /791	Reference	19.4632	Reference	Reference	97,199,068 /657,461
Every 5-year screening strategy (40 years old)	Undominated	144,615 /978	27,655 /187	19.5066	0.0434	637,874 /4,315	97,388,189 /658,741
Every 4-year screening strategy (40 years old)	Undominated	147,443 /997	2,827 /19	19.5098	0.0032	871,875 /5,897	97,401,578 /658,831
Biennial screening strategy (40 years old)	Undominated	203,815 /1,379	56,372 /381	19.5124	0.0026	21,863,477 /147,886	97,358,097 /658,537
Annual screening strategy (40 years old)	Undominated	321,606 /2,175	117,791 /796	19.5131	0.0007	173,642,337 /1,174,529	97,243,698 /657,763

Results: A simulation model was constructed based on the cohort data of 94,137 participants (mean age 54.5 years, males 57.9%; 74.4% *H. pylori*-naïve, 94.2% intestinal metaplasia-negative). The results of the base-case analysis showed that the screening strategy of 4-year intervals starting at the age of 40 years had the highest net monetary benefit (97,401,578 yen) (Table). Based on the Monte Carlo simulation, the cost-effectiveness acceptability curve demonstrated that the 4-year interval screening strategy starting at the age of 40 years was superior to the other strategies when the willingness-to-pay was set at 5,000,000 yen. In one-way sensitivity analysis with a varying probability of *H. pylori* infection status transition, the incremental cost-effectiveness ratio was superior in the screening strategy every 4 years, starting at age 40 years.

Conclusion: Gastric cancer screening strategies can be modified in terms of cost-effectiveness in a modern Japanese cohort. Our simulation showed that endoscopic screening at 4-year intervals starting at 40 years was the most cost-effective method.

Introduction: Current risk stratification of Barrett's esophagus (BE) patients, based on histological identification of dysplasia, lacks reliability due to poor interobserver agreement and the limited predictive value of low-grade dysplasia (LGD).

Aims & Methods: This study aims to identify genomic factors enhancing risk stratification for BE patients with a community diagnosis of LGD.

Progressors to early esophageal adenocarcinoma and non-progressors were identified in a randomized controlled trial screening cohort of community-based LGD patients. Sequencing used a targeted capture-based panel to detect mutations and copy number changes (CNV). Detected mutations, homozygous deletions, and high-level amplifications underwent filtering for likely pathogenic events. We performed logistic regression, covariate analysis, and penalized mixed-effect models. A joint model for survival and mixed effects was applied for spatiotemporal data analysis. The model's performance was compared with that of general and expert pathologists to evaluate its clinical relevance.

Results: 220 samples, comprising 28 progressors with a median time to progression of 1.2 (IQR 0.4-2.2) years and 95 non-progressors with a median progression-free follow-up of 7.9 (IQR 5.9-10.6) years, all with a median C3M5 BE, were analyzed. Multiple factors were associated with progression, including *TP53* ($p < 0.0001$, Hazard Ratio (HR) = 13.39, 95% confidence intervals (CI) 5.64-31.78), chromosomal arm 17p loss ($p < 0.0001$, HR = 10.24, 95% CI 4.82-21.76), mutational burden ($p < 0.001$, HR = 1.52, 95% CI 1.21-1.90), and total number of CNVs ($p < 0.0001$, HR = 1.48, 95% CI 1.34-1.64). Several other alterations trended to be associated with progression, including *APC* mutation and presence of an oncogenic amplification. The combined influence of *TP53* and 17p loss enhanced the accuracy of risk prediction. However, high correlation precluded their use as cumulative risk. Patients with samples containing ≥ 3 mutations had a very high risk of

progression (HR = 10.33, 95% CI 2.22-48.01). Presence of any genetic variant—amplification, deletion, CNV, or mutation— indicated progression risk (p<0.0001, HR = 1.15, 95% CI 1.11-1.21). Samples lacking any genetic variants showed no progression. A combined *TP53* and CNV model effectively identifies progression risk with a sensitivity of 64.3%, specificity of 94.7%, and an AUC of 0.837, distinguishing 89 out of 94 non-progressors. In contrast to traditional assessments, this model demonstrates substantial improvements (p=0.002) compared to the expert pathologist assessment (median sensitivity of 67.9 % [0.321, 0.821], median specificity of 80.4% [0.606, 0.957], k value: 0.47).

	Predicted non-Progressive	Predicted Progressive
True Non- Progressors	91	4
True Progressors	10	18

Conclusion: This study not only reinforces the well-established role of *TP53* mutations but also introduces crucial novel genomic markers. The addition of 17p loss emerges as indispensable for enhanced risk assessment.

Furthermore, distinct genetic variations, including CNVs and total mutations, individually and collectively signify a significantly higher risk. Intriguingly, patients without any distinctive genetic abnormalities did not progress. A combined genomic model could consistently accurately risk stratify BE patients with a community-based LGD diagnosis, highlighting its enhanced and reliable predictive accuracy.

Introduction: Oxyntic gland neoplasms (OGNs) are rare gastric lesions that mainly show differentiation to chief cells [1, 2]. In the fifth edition of the WHO classification, the OGN entity includes oxyntic gland adenoma and gastric adenocarcinoma of fundic gland type [3]. Though these subtypes are classically considered more benign, interest has been developing in a third group, gastric adenocarcinoma of fundic-gland mucosa type (GA-FG-M). GA-FG-M are distinct among OGN in that they more commonly show lymphovascular invasion on histology and are thus considered more aggressive lesions with higher malignant potential. Although interest in OGNs has been gradually increasing in the past few years, most studies had involved cases collected by tertiary referral centers, leading to a gap in the knowledge of the true disease frequency in the real-world setting. To address this issue, we previously reported the incidence of OGNs in 7488 patients in a large outpatient clinic in Japan between 2017 and 2021. However, the absolute number of OGNs was limited and the incidence of GA-FG-M was unknown [5].

Aims & Methods: The goal of this study was to more accurately characterize the disease frequency and clinicopathological characteristics of OGNs by including more than three times the number of lesions discovered since the previous report. We also aim to include an estimate for the GA-FG-M subtype. All upper gastrointestinal endoscopies performed at a high-volume outpatient clinic between December 2017 and December 2023 were retrospectively reviewed, and new cases of histologically diagnosed OGN were identified. Patient demographics, endoscopic and histopathological details are presented.

Results: During the study period, 9431 patients underwent 22322 procedures, with 85 patients having a total of 106 OGNs, resulting in a point prevalence of 0.9% (85/9431). GA-FG-M was identified in 3 patients, leading to a prevalence of 0.03% (3/9431). Fifteen patients (18%) had multiple lesions simultaneously or metachronically. Forty-six patients (54%) had a history of *H. Pylori* infection. Forty-nine lesions underwent endoscopic management, with 11 resected via ESD and 38 via EMR-C. The median tumor diameter was 3mm (range 2-9). Fourteen of the resected lesions had evidence of submucosal involvement. In this subset, the deepest penetration ranged from 10-950um into the submucosal layer. Median Ki67 index value was 2% (range 1-15). Thus far, there has been no evidence of recurrence on clinical follow up.

Conclusion: Though the most recent WHO classification states the prevalence of OGNs remains unknown [3], our data supports that these lesions are more common than once thought. Initial reports had suggested rates of <0.01% [6], and our previous study had found a community point prevalence of 0.36% [5]. However, in two years since that study period, the amount of lesions identified has more than tripled, leading us to a more accurate prevalence estimate of 0.9%. In addition, we clarified the prevalence of GA-FG-M to be 0.03%. It is possible this number may continue to rise in the future, as knowledge about this atypical form of gastric neoplasia is further disseminated amongst gastroenterologists and pathologists.

SLC26A9 GOVERNS GASTRIC PARIETAL CELL IDENTITY AND FUNCTIONS AS AN IMPORTANT PROTECTIVE ROLE IN THE INJURY-INDUCED METAPLASIA

Z. Ma¹, E. Wu^{2,3}, T. Li³, B. Tuo³, X. Liu⁴

¹Department of Gastroenterology, Affiliated Hospital of Zunyi Medical University, Zunyi, China, ²Affiliated Hospital of Zunyi Medical University, Zunyi, American Samoa, ³Affiliated Hospital of Zunyi Medical University, Zunyi, China, ⁴Affiliated Hospital of Zunyi Medical University, Hannover, China

Introduction: Gastric injury induces metaplasia is based on parietal cells loss and reprogramming chief cells into proliferative, mucin-rich spasmolytic polypeptide-expressing metaplasia (SPEM) cells. Previously, we demonstrated that parietal cell-selective Slc26a9 deficiency in mice promotes the development of SPEM and progress to gastric intraepithelial neoplasia in mice (Liu et al., Cellular oncology; 2022; Deng et al., DDW2023). However, the exact role of Slc26a9 in injury-induced metaplasia is need further investigated.

Aims & Methods: We used immunostaining to characterize the expression pattern of Slc26a9 during murine gastric development, homeostasis, and injury in homeostasis, after conditional genetic deletion of Slc26a9. Furthermore, to reveal the functional role of Slc26a9, Injury-induced metaplasia was established in Slc26a9^{fl/fl} mice and Slc26a9^{fl/fl}/Atp4b-Cre mice with high-dose tamoxifen.

Results: Mice with parietal cell selective Slc26a9 deficiency first developed spontaneous parietal cell damage, which subsequently led to SPEM. Parietal cell injury was associated with the release of typical pyroptosis factors, including NLRP3, Caspase-1, ASC, GasderminD, IL-1 β and IL-18. At the same time, SLC26A9 colocalized with caspase1, NLRP3, GSDMD, and NLRP3 and GSDMD, and produced a large number of reactive oxygen species (ROS), markers of mitochondrial damage, thereby expanding membrane perforation of GSDMD-N fragments and amplifying inflammasome-mediated parietic cell pyrodeath. At the same time, electron microscopy showed that after the knockout of the Slc26a9 gene, the mitochondria of the murine wall cells were obviously swollen, the cell membrane structure was blurred and damaged, the matrix was more dissolved, the ridge was broken and disappeared, and there were many bubble protrusions. This suggests that parietal cell specific SLC26A9 gene deletion may lead to parietal cell scorch death through mitochondrial damage mediated by GSDMD. However, with a large number of parietal cell damage and loss, gastric hypergastrinemia stimulates Tuft cell proliferation and migration to the gastric mucosa for colonization, and secretes a series of alarm hormones such as IL-25, IL-33, HMGB1.

Moreover, ILC2 cell secretory factors such as IL-17RA and IL-17RB, GATA3, CD90, CD25 were up-regulated. M2 macrophage polarization-related markers such as Arg1, Fizz1, Ym1, Klf4 and secreted chemokines such as CCL24 and CCL22 were significantly up-regulated. The immunofluorescence staining of F4/80+ and CD163+ was significantly increased. This suggests that the spontaneous injury of parietal cells caused by the deletion of SLC26A9 gene in gastric parietal cells may lead to gastric dysfunction (hypoacid and hypergastrinemia) and mucosal epithelial injury, which may promote the occurrence of SPEM through IL-25 mediating the activation of ILC2 cells to regulate the cellular immune mechanism of macrophage M2 polarization.

Conclusion: Slc26a9 target deletion in parietal cells leads to spontaneous damage and scorch death of parietal cells, which is the core target and cell origin of initiating SPEM. After parietal cell specific Slc26a9 gene deletion leads to spontaneous injury of parietal cells, gastric dysfunction and mucosal injury result in the release of alarm hormone IL-25, which pro-

motes the development of SPEM by activating IL-25-ILC2-macrophage M2 polarization axis. Slc26a9 plays an important protective role in stabilizing gastric epithelial cell differentiation and gastric mucosal immune homeostasis.

Introduction: During gastric cancer (GC) progression, two types of metaplasia, spasmolytic polypeptide-expressing metaplasia (SPEM) and intestinal metaplasia (IM), are considered key pre-tumour events crucial for malignant transformation to GC. Currently, no effective therapeutic strategies target these events.

Aims & Methods: This study was performed to investigate the inhibitory efficacy and mechanism of action of luteolin (Lut) on SPEM and IM. An in vivo SPEM model was established by intraperitoneal injection of high-dose tamoxifen (TAX) in mice, and the IM models were established by treating GES-1 cells and rats with chenodeoxycholic acid (CDCA). To reveal the mechanism of action of Lut, we performed transcriptomic analysis of Lut-treated gastric corpus specimens, and quantitative chemoproteomic profiling to identify key targets of Lut.

Results: Lut-treated mice exhibited remarkable resistance to oxyntic atrophy and emergence of SPEM. Significant numbers of Lut-treated rats entered remission from IM. Transcriptomic analysis revealed that up-regulated LCN2 expression in the injured mucosal region in SPEM model mice could be downregulated by Lut. LCN2 knockdown also inhibited high-dose TAX-induced SPEM formation. Quantitative chemoproteomic profiling results suggest that STAT3 is a key target of Lut and that STAT3 inhibition partially abolishes the beneficial effect of Lut.

Conclusion: Lut is a novel therapeutic candidate for SPEM and IM that can target STAT3 by downregulating LCN2 expression. These findings reveal a novel strategy for inhibiting gastric precancerous conditions.

Introduction: Endoscopic submucosal dissection (ESD) has evolved to become a viable treatment option for oesophageal squamous dysplasia (SD) and early squamous cell carcinoma (ESCC). Although en bloc, R0, excision has the potential to yield an endoscopic cure, surgery remains the standard of care in the West. Furthermore, Western data pertaining to endoscopic outcomes is limited. We aimed to assess the efficacy and safety of ESD for SD and ESCC in a single tertiary referral centre.

Aims & Methods: We conducted a prospective observational cohort study over 87 months until November 2023 in consecutive patients undergoing ESD for SD or ESCC. The primary outcomes were enbloc, R0 and curative resection rates. Secondary outcomes included procedure duration, tumor recurrence and adverse events.

Results: 112 consecutive patients were referred for treatment and underwent ESD (median age 73 [IQR 68-78]; 50% male; Table 1). Median lesion size was 30 mm (IQR 20-50mm) and Paris IIa was the most common morphology (58.9%). Enbloc resection was achieved in 109 (97.3%) and R0 excision in 87 (77.7%). Curative resection in cases of LGD and HGD, where margins were clear of dysplasia, was 7/11 (63.6%) and 31/34 (91.2%) respectively. In those with T1a/T1b SCC, the curative resection rate was 20/61 (32.8%). In T1a SCC lesions, 11/20 (55.0%) had a curative ESD. Of the remainder, 6/9 were poorly differentiated, 1/9 had LVI, and 2/9 had positive margins (1 deep, 1 peripheral). In T1b SCC lesions, 9/41 were curative (22.0%). The remainder were either poorly differentiated, >T1b-SM1, LVI positive or a combination. In those with T1a/T1b disease, without adverse tumor biology, ESD achieved curative resection in 20/22 (90.9%). In the 41/61 (67.2%) T1a/T1b patients that did not meet criteria for cure, subsequent treatment included surgery (n=5), radiotherapy (n=5) and chemoradiotherapy (n=1). After MDT discussion, the remaining 30 were managed conservatively, due to advanced age or comorbidities. In these, recurrence occurred in 6/30 patients (1 local, 3 nodal, 2 metastatic) at a median follow up of 12 months (6-18 months). The median hospital length of stay was 1 day (IQR 1-3). Oesophageal strictures occurred in 46 patients (41.1%), requiring a median of 3 dilations (IQR 1-8). There were 2 cases of delayed bleeding. There were no perforations.

	Median (IQR) OR n (%)
Age (years)	73 (IQR 68-78)
Male gender	56 (50%)
Lesion Size (mm)	30 (IQR 20-50)
Morphology (Paris classification)	
Paris IIa	66 (58.9%)
Paris Is / IIa+Is	20 (17.9%)
Paris IIb	17 (15.2%)
Paris IIc component	8 (6.2%)
Other	1 (0.9%)
Histology	
Reactive squamous hyperplasia	6 (5.4%)
Low grade dysplasia	11 (9.8%)
High grade dysplasia	34 (30.4%)
T1a squamous cell carcinoma	20 (17.9%)
T1b squamous cell carcinoma	41 (36.5%)
ESD defect length (cm)	7 (IQR 5-9)
ESD defect circumferential extent (%)	60 (IQR 50-83.3)
Procedure duration (mins)	90 (IQR 60-120)
Hospital length of stay (days)	1 (IQR 1-3)

Table 1.

Conclusion: ESD is curative for low and high-grade dysplasia. In a Western setting, ESD offers definitive T-staging and has the potential to yield a cure in almost 33% of T1a and T1b SCC cases. Due to a high risk of disease recurrence, adjuvant therapy should be considered in cases of a non-curative resection.

FOXC1 MAY UNDERGO LIQUID-LIQUID PHASE SEPARATION AND INVOLVED IN THE DEVELOPMENT OF GASTRIC CANCER

W. Jing^{1,2,3}, K. Deng^{2,3}, J. Yang^{2,3}

Introduction: Recently, liquid-liquid phase separation (LLPS) of transcription factor has been found to play a critical role in the development of tumors [1-3]. Meanwhile, Forkhead box C1 (FOXC1), a transcription factor protein with intrinsically disordered regions (IDRs), is related with the prognosis of gastric cancer [4]. However, whether FOXC1 could undergo LLPS and whether FOXC1 involved in the development of gastric has not been studied until now.

Aims & Methods: Therefore, we aimed to investigate whether FOXC1 could undergo LLPS and the potential role of FOXC1 in gastric cancer. We analyzed different expression gene of gastric cancer samples from The Cancer Genome Atlas dataset and the sequencing results of our own samples. The protein sequence prediction website (Disprot - Database of Protein Disorder) was used to predict the IDRs of FOXC1. Besides, fluorescence recovery after photobleaching (FRAP) and cellular immunofluorescence were used to explore whether FOXC1 could undergo LLPS. What's more, cell proliferation assay, cell apoptosis assay and cell migration assay were utilized to investigate the potential role of FOXC1 in gastric cancer.

Results: In the different expression gene analysis of the TCGA database and our own data, it was found that the expression level of FOXC1 in gastric cancer was significantly higher than that of paracancer tissue (Figure 1 A-B), which was proved by RTq-PCR (Figure 1 C). Knockdown of FOXC1 in gastric cancer cell resulted in decreased proliferation (Figure 2A), decreased migration (Figure 2B), and increased apoptosis (Figure 2C). In the prediction of protein structure, it can be found that the IDRs region of FOXC1 accounts for more than 50% (Figure 3).

After the fluorescence bleaching of the droplet formed by FOXC1 with Ac-GFP in AGS cell, the fluorescence gradually recovers within a few minutes (Figure 4C). What's more, endogenous FOXC1 could form puncta with irregular distribution in nuclear (Figure 4D), which also proves that FOXC1 can undergo LLPS.

Conclusion: Overall, knockdown of FOXC1 in gastric cancer cell can inhibit the development of gastric cancer by decreasing proliferation and migration, increasing apoptosis. FOXC1 can also undergo LLPS in vitro and in vivo. Therefore, we speculate that FOXC1 may promote the development of gastric cancer through LLPS.

Introduction: The asymptomatic nature of precancerous lesions, namely low- and high-grade dysplasia (LGD and HGD, respectively), constitutes a major clinical challenge that precludes a timely detection of gastric cancer (GC) in curable stages. The identification of novel and accurate biomarkers holds the promise of a better risk assessment and citizens stratification for an early diagnosis. In this exploratory study, we proposed to characterize the transcriptomic landscape of gastric lesions (GL) towards the definition of a molecular profile for early screening of GC in Western populations.

Aims & Methods: RNA-Sequencing analysis was conducted on RNA extracted from 39 formalin-fixed paraffin-embedded (FFPE) samples: 20 “normal-appearing” mucosa controls and 19 gastric lesions (GL), including LGD, HGD, and adenocarcinoma. Differential expression analysis, functional enrichment analysis, least absolute shrinkage and selection operator (Lasso) regression, and the machine-learning extreme gradient boosting (XGBoost) algorithm were employed to identify potential biomarkers and assess the predictive value of the molecular signature of the top dysregulated genes.

Results: A total of 1171 differentially expressed genes (DEGs) were identified in GL. Remarkably, 867 of these genes (74%) showed exclusive dysregulation in lesions compared to stage I GC samples from The Cancer Genome Atlas (TCGA) stomach adenocarcinoma (STAD) cohort. These unique biomarkers predominantly participate in translation, as well as metabolic and biosynthetic processes. In contrast, DEGs from TCGA-STAD cohort were primarily enriched in immunity-related processes. Notably, the eight best genes model, comprising *ADAMTSL1*, *CLDN2*, *ENC1*, *GSR*, *IQNC*, *PER1*, *PRR33*, and a novel transcript corresponding to a long non-coding RNA (lncRNA, ENSG00000227218), achieved an area under the curve (AUC) of 0.938 (95% CI: 0.815-1.000), with a sensitivity of 87.5% and specificity of 100% to classify GL samples.

Conclusion: This preliminary study identified over 800 DEGs exclusively in GL compared to stage I GC. Moreover, it unveiled a molecular-based signature that effectively discriminates patients with GL in an intermediate-risk

population. This discovery paves the way for enhancing early GC screening strategies, particularly for those who can be treated through minimally invasive, nonsurgical procedures.

Disclosure: Nothing to disclose.

Introduction: Oesophageal squamous cell carcinoma (OSCC) represents approximately 90% of the nearly half-million annual cases of oesophageal cancer globally. The invasiveness and high costs associated with traditional upper endoscopy limit its use in the routine surveillance of at-risk populations, including individuals with a history of head and neck cancer (HNC). Previous data suggest that copy number abnormalities (CNAs) are a feature of OSCC development.

Aims & Methods: This study explored the efficacy of shallow whole-genome sequencing (sWGS) to detect genome-wide CNAs in cells collected using a non-endoscopic sponge pan-oesophageal sampling device. Our objective was to develop and validate a predictive model for the early detection of oesophageal squamous dysplasia and neoplasia, aiming to improve disease prognosis through timely intervention.

We prospectively collected oesophageal specimens from 178 participants using the Cytosponge device as part of the EDEN and OSCAR projects: OSCC (n = 24), high-risk individuals (n = 61), and healthy controls with dyspeptic symptoms (n = 93). The samples underwent 1.5-2x sWGS as well as H&E staining for atypia assessment and p53 immunohistochemistry (IHC) which were performed by two gastrointestinal (GI) pathologists who were blinded to the reference endoscopic diagnoses. Through penalised regression analysis, we identified significant CNAs indicative of dysplasia or early neoplasia. These critical genomic insights were then used to develop and refine a logistic regression model aimed at predicting dysplasia or early neoplasia in cytosponge-derived specimens. The predictive accuracy of the model was subsequently confirmed through validation against sWGS in microdissected ESD samples which represented known pathological states.

Results: Key genomic indicators for oesophageal squamous dysplasia and early neoplasia were identified, including significant CNAs in chromosome arms chr2q, chr3q, chr9p, and chr11q along with the Genome-Wide Instability Score (GWIS), a percentage-based metric quantifying genomic instability across the genome. Our logistic regression model, which integrated these genomic biomarkers, achieved an Area Under the Receiver

Operating Characteristic Curve (AUROC) of 0.947, with sensitivity and specificity rates of 89% and 88.2%, respectively. This model outperformed another that utilised only pathological data (definite squamous atypia and p53 IHC), which achieved an AUROC of 0.880, with a sensitivity and specificity of 83.6% and 84.6%, respectively. However, when pathological data were combined with the genomic indicators, the diagnostic performance of our model improved significantly, resulting in an AUROC of 0.969 with enhanced sensitivity and specificity of 95.9% and 90.5%, respectively. Further validation of the genomic model against microdissected ESD samples with known pathological states reinforced its robustness, achieving an AUROC of 0.879, which improved to 0.905 when low grade dysplasia (LGD) samples were excluded, highlighting the diagnostic challenges and variability in LGD classification.

Conclusion: The integration of shallow whole-genome sequencing with non-endoscopic sponge sampling has the potential for the early detection of OSCC. This approach is particularly valuable in high-risk populations and settings where traditional endoscopy is impractical.

Introduction: The prevalence of celiac disease is increasing and represents a growing global health issue. The disease profoundly affects patients' quality of life through the multitude of symptoms and complications, as well as the necessity for strict adherence to a gluten-free diet. Gastroenterologists face persistent challenges in diagnosing and managing celiac disease amidst its complexities.

In this context, the integration of artificial intelligence (AI) emerges as a promising advancement, offering potential to revolutionize the landscape of celiac disease management.

Our objective is to evaluate the effectiveness of AI as a reliable and useful asset for patients and gastroenterologists in the management of celiac disease.

Aims & Methods: Research was carried out on the Google Trends website to identify the 5 most searched-for keywords (from 2004 to March 2024) related to celiac disease: gluten-free diet, diagnosis, serologies, associated diseases, complications.

We asked 10 gastroenterologists and 10 celiac patients to formulate all the questions they had about celiac disease in relation to these key words. Eighty questions were generated based on their responses (40 questions formulated by each group).

The questions were inputted into the "prompt" section of an artificial intelligence (Google GEMINI version 20/02/2024) and the answers were evaluated using a 7-point Likert-type reliability and usefulness scale by two independent celiac disease experts.

Statistical analyses were performed using JAMOVI version 2.3 software. Inter-observer agreement was assessed using Intra-class correlation coefficient [ICC], and Student t-test was used to compare differences between two groups. The significance level for this study was set at $p < 0.05$.

Results: The intra-class correlation coefficient values for both reliability and usefulness scores demonstrated excellent agreement between the two experts.

Indeed, for answers intended to help gastroenterologists, we observe (Reliability: ICC=0.918, 95% CI : 0.852-0.956 Usefulness: ICC=0.887, 95% CI : 0.798-0.939).

For answers intended for celiac patients (Reliability: ICC=0.935, 95% CI : 0.881-0.965 and ICC=0.926, 95% CI : 0.865-0.960)

The average scores given by experts n°1 and n°2 were: Reliability 4.83 ± 1.58 vs. 5.03 ± 1.54 ($p=0.04$) and Usefulness 4.75 ± 1.39 vs. 5.00 ± 1.26 ($p=0.01$), suggesting that AI had limitations in providing reliable but also useful answers to healthcare professionals about celiac disease.

However, when it came to answering celiac patients' questions, we noted that AI gave better scores, this time with no statistically significant difference between the two experts: 5.60 ± 1.15 vs 5.63 ± 1.17 ($p=0.78$) and 5.67 ± 1.33 vs 5.78 ± 1.27 ($p=0.23$).

Finally, there was a statistically significant difference between the two groups (gastroenterologist and celiac patients), concerning the reliability and usefulness of AI responses for expert n°1 ($p=0.008$ and $p=0.001$ respectively) as well as for expert n°2 ($p=0.045$ and $p=0.003$ respectively).

Conclusion: The results suggest that AI, particularly Google GEMINI, can

be a particularly useful tool in managing celiac disease, especially for celiac patients, by providing reliable and useful answers to questions related to gluten-free diet, diagnosis, serologies, associated diseases, and complications. However, the results are less satisfactory when it comes to answering healthcare professionals, highlighting the need for constant updates and reliance on reliable and up-to-date sources.

Introduction: Accurate estimation of cancer risk in patients with Barrett's esophagus (BE) and low-grade dysplasia (LGD) or indefinite for dysplasia (ID) is difficult, leading to potential under- and over-treatment. We aimed to evaluate the utility of machine learning (ML) and copy number alterations (CNAs) assessed by shallow whole genome sequencing (SWGS) on standard formalin-fixed paraffin-embedded (FFPE) samples for precise risk stratification in this group of BE patients.

Aims & Methods: We conducted a retrospective analysis on a cohort of 164 BE patients encompassing 990 tissue samples with SWGS (~0.4X) data from 2001-2018. These included 215 samples with LGD or ID from 64 patients, of which 38 progressed to high-grade dysplasia (HGD) or cancer at later timepoints (P), and 26 who did not progress (NP). CNAs were quantified using QDNASeq, and outlier bins were determined by Tukey's fences. Subsequently, the CNAs of 64 esophageal cancer driver genes were compared between P and NP groups using t-tests and ranked by p-values. A random forest (RF) ML model was developed on the CNAs of the 64 genes, employing nested 5-fold cross-validation split by patients and iterated 100 times to mitigate bias. The model's performance was compared against routine p53 immunohistochemistry (IHC), a decision tree that incorporates p53 followed by the ML model, and the current ESGE clinical guideline recommending treatment after LGD is identified in two endoscopies. Both the model and model+p53 were assessed across 100 test sets derived from the cross-validation.

The guideline's performance was evaluated using a historical extended cohort comprising 253 LGD patients, of which 32 progressed, and underwent at least one surveillance endoscopy after LGD diagnosis and before HGD/cancer diagnosis. According to the guideline, two occurrences of LGD result in a positive prediction.

Results: Significant variance was observed in the distribution of relative CNAs across genomic bins between P- and NP-LGD/ID samples, with the proportions of outliers at 2.15% (95% CI: 1.88%, 2.42%) vs. 1.35% (95% CI: 1.26%, 1.44%).

The most divergent genes included TP53, ABCB1, MET, BRAF, and SIN3A, exhibiting higher CNAs in progressed samples. Among the 215 samples, the RF model achieved an average sensitivity of 73.4% and specificity of 80.2%.

Of these, 160 samples were tested for p53 IHC staining, where p53 alone showed a sensitivity of 22.1% and specificity of 100%, and a combined analysis of p53 and model increased the sensitivity of model alone (81.5% vs. 78.1%, $p<0.001$) while maintaining the same specificity at 78.9%. As a benchmark, the performance of the current ESGE guideline on biopsy diagnosed LGD patients demonstrated a sensitivity of 75.0% and specificity of 59.6%.

Conclusion: Our findings affirm the utility of ML and CNAs in predicting progression in BE patients with LGD or ID. Incorporating p53 followed by ML can further improve the performance. Molecular biomarkers would allow anticipation of intervention in high-risk cases and reduction of over-treatment in low-risk cases.

Introduction: Artificial intelligence (AI) algorithms aid endoscopists in detecting and characterizing colonic polyps in clinical practise and lead to an improved adenoma detection rate. AI may also support therapeutic procedures by detecting and marking anatomical structures during complex procedures like endoscopic submucosal dissection (ESD) ¹. However, a possible effect of AI on the intraprocedural blood vessel detection rate during third space endoscopy remains unclear.

Aims & Methods: This study aimed at evaluating the impact of a newly developed AI algorithm for real time intraprocedural vessel detection on the vessel detection performance of endoscopists during ESD. To this end, 5470 single images from 59 full length third space endoscopy videos were annotated for submucosal blood vessels. Together with 179681 additional unlabeled images this dataset was utilized for the training of a DeepLabV3+ neural network. The trained algorithm detected and marked submucosal blood vessels on the endoscopic image in real time. Consequently, a video test consisting of 101 video clips with 200 predefined blood vessels was used for the evaluation of the algorithm alone, as well as 19 endoscopists with and without AI support.

Results: The algorithm showed a vessel detection rate (VDR) of 93.5% and a median vessel detection time (VDT) of 0.3 sec. AI support was associated with an elevation of endoscopists' VDR from 56.4% to 72.4% ($p<0.001$). VDT decreased from 6.7 to 5.2 sec with AI support ($p<0.001$). False positive detections were measured on 4.5% of single frames. They had a significantly shorter duration than true positive findings (0.7 vs. 6.0 sec, $p<0.001$).

Conclusion: AI support led to increased VDR and reduced VDT of endoscopists. False positive findings were easily distinguishable from true positives by their short duration. Future research may elucidate a possible

effect of AI on clinical parameters like intraprocedural complication rates or procedure times.

DIFFERENT BIOPSY RATE BRINGS DIFFERENT APPLICATION EFFECTIVENESS FOR ARTIFICIAL INTELLIGENCE DEVICE IN DETECTING GASTRIC NEOPLASMS IN REAL WORLD

L. Huang¹, L. Wu², H. Yu³

¹Renmin Hospital of Wuhan University, Wuhan, China, ²Renmin Hospital of Wuhan university, Wuhan, China, ³Renmin Hospital of Wuhan University, Gastroenterology, Wuhan city, China

Contact E-Mail Address: huangli9707@163.com

Introduction: The implementation of computer-aided detection (CAD) devices in esophagogastroduodenoscopy (EGD) could autonomously identify gastric precancerous lesions and neoplasms, and reduce the miss rate of gastric neoplasms in prospective trials. However, there is still insufficient evidence of their use in real-life clinical practice.

Aims & Methods: A real-world, two-center, large-volume, pragmatic study was conducted at Wenzhou Central Hospital (WCH) and Renmin Hospital of Wuhan University (RHWU). Random biopsy and target biopsy were adopted and CAD devices were applied in 2019 and 2021 at WCH and RHWU, respectively. We compared differences in gastric precancerous and neoplasm detection of EGD before and after the use of CAD devices in the first half of the year.

Results: A total of 33885 patients were included and 32886 patients were ultimately analysed. In WCH of which biopsy rate > 95%, with the implementation of CAD, more early gastric cancer detection rate (0.35% vs. 0.59%, $p=0.028$, $OR(95\%CI) = 1.65(1.06-2.60)$) was found while gastric neoplasm detection rate (1.39% vs. 1.36%, $p=0.897$, $OR(95\%CI) = 0.98(0.76-1.26)$) remained stable. In RHWU of which biopsy rate < 20%, the gastric neoplasm detection rate (1.78% vs. 3.23%, $p<0.001$, $OR(95\%CI) = 1.84(1.33-2.54)$) nearly doubled after the implementation of CAD while there was no significant change in the early gastric cancer detection rate.

Conclusion: In our study of large-volume tertiary centers with varied biopsy strategies, we observed that diagnostic benefits differed depending on the application conditions, and each biopsy approach offered distinct advantages. In healthcare center with a high biopsy rate exceeding 95%, the CAD device appeared to enable endoscopists to conduct more precise, targeted biopsies, leading to an increased detection of early gastric cancer. However, the overall gastric neoplasm detection rate remained consistent. In contrast, at institutions like RHWU, which employed a targeted biopsy strategy resulting in an average biopsy rate less than 20%, the incorporation of CAD in routine EGD demonstrated a notable increase in the overall gastric neoplasm detection rate, particularly for low-grade intraepithelial neoplasia.

Introduction: Acute gastrointestinal bleeding (GIB) is a common reason for hospitalization, with a 2%–20% risk of mortality. Identification of patients at high risk of death is essential to make fast and adequate decisions on their management.

Aims & Methods: We developed two machine-learning (ML) models to calculate the risk of in-hospital mortality in patients admitted due to overt GIB.

The prospective, multicenter Hungarian GIB Registry's data were analyzed. We focused on in-hospital mortality and applied statistical binary classification. The predictive performance of XGBoost and Catboost machine-learning algorithms was compared with the Glasgow-Blatchford (GBS) and pre-endoscopic Rockall scores. We evaluated our models using five-fold cross-validation, and performance was measured by area under receiver operating characteristic curve (AUC) analysis with 95% confidence intervals (CI). The individual predictions and the variables' contribution to the outcome were calculated via the SHapley Additive exPlanations (SHAP) method.

Results: Overall, we included 1,021 patients in the analysis; 52% had nonvariceal upper GIB, 30% had lower GIB, and 9% had variceal bleeding. The median age was 70 years; 60% were men. In-hospital death occurred in 108 cases (11%). We selected 19 of 96 input variables in both final ML

models. The XGboost and the Catboost model identified patients who died with an AUC of 0.84 (CI: 0.76-0.90; 0.77-0.90; respectively) in the internal validation set, whereas the GBS and pre-endoscopic Rockall clinical scoring system's performance was significantly lower, AUC values of 0.68 (CI: 0.62 - 0.74) and 0.62 (CI: 0.56 - 0.67), respectively. The XGBoost model had a specificity of 0.96 (CI: 0.92-0.98) at a sensitivity of 0.25 (CI: 0.10-0.43) compared with the CatBoost model, which had a specificity of 0.74 (CI: 0.66-0.83) at a sensitivity of 0.78 (CI: 0.57-0.95). In the CatBoost model, the most influential variables contributing to the prediction were CRP level, smoking, melena, minimum systolic blood pressure, previous GIB, Glasgow Coma Scale and hemoglobin level.

Conclusion: The new ML models identified patients with high mortality risk significantly better than GBS and pre-endoscopic Rockall scores. Due to its better sensitivity, we prefer the CatBoost model in determining the in-hospital mortality risk of GIB.

HUMAN-COMPUTER INTERACTION: EXAMINING THE INFLUENCE OF ARTIFICIAL INTELLIGENCE ON THE DIAGNOSTIC CONFIDENCE OF ENDOSCOPISTS IN THE EVALUATION OF BARRETT'S ESOPHAGUS

D.A. Roser¹, M. Meinikheim¹, R. Mendel², C. Palm², A. Muzalyova¹, D. Rauber², T. Rückert², N. Parsa^{3,4}, M. Byrne^{4,5}, H. Messmann¹, A. Ebigbo¹

Introduction: Human-computer interactions (HCI) can substantially influence the performance of Artificial Intelligence (AI). Studies indicate that although endoscopists, when assisted by AI, demonstrate significant improvements in assessing Barrett's esophagus (BE), their performance does not reach the stand-alone level achieved by AI. A critical aspect of HCI is the impact of AI on the certainty and confidence exhibited by endoscopists. Indirectly, diagnostic confidence when utilizing AI may be associated with the trust and acceptance of AI. In a study focusing on BE videos, our objective was to examine the influence of AI on endoscopists' diagnostic confidence and explore potential correlations with diagnostic performance.

Aims & Methods: Twenty-two endoscopists from twelve centers, with varying levels of BE experience, reviewed ninety-six standardized endoscopy videos. The endoscopists were categorized as experts and non-experts and were randomly assigned to evaluate the videos with and without AI. Participants were divided into two arms: Arm A assessed videos initially without AI and then with AI, while Arm B followed the opposite order. Evaluators were tasked with identifying BE-related neoplasia and providing confidence ratings both with and without AI on a scale from 0 to 9. The study was followed up by a survey.

Results: In Arm A (without AI first, with AI second), the use of AI significantly increased confidence levels for both experts and non-experts ($p < 0.001$). Notably, only non-experts experienced a significant improvement in sensitivity and specificity ($p < 0.001$ bzw. $p < 0.05$) with the assistance of AI. While experts exhibited higher confidence levels without AI compared to non-experts with AI, there was no significant difference in accuracy be-

tween these two groups. In Arm B both groups demonstrated a significant reduction in confidence ($p < 0.001$), while maintaining consistent accuracy levels. In addition, in 9% of the choice changes with AI, the wrong choice was made despite correct indications made by AI.

Conclusion: AI significantly boosted confidence levels for both expert and non-expert endoscopists - an effect that was reversible in the study model. Furthermore, experts consistently displayed higher confidence levels, with or without AI, compared to non-experts with AI, despite comparable outcomes. It was further observed that in 9% of the choice changes the investigators ignored the AI in disadvantage of the patient. These findings highlight the potential role of AI in enhancing diagnostic confidence during endoscopic assessments.

Disclosure: Nothing to disclose.

Contact E-Mail Address: mandarino.francesco@hsr.it

Introduction: Accepted oncological principles advise enbloc, R0, excision of cancer to provide a cure. In Barrett's neoplasia, this includes T1a and T1b disease, where histology is favorable. While treatment options include endoscopic mucosal resection (EMR) and submucosal endoscopic dissection (ESD), a mechanism for appropriate technique selection has not been described.

Aims & Methods: We conducted a prospective observational study to evaluate the performance of a selective resection algorithm for Barrett's neoplasia (SRAB). To achieve an enbloc resection, ESD was selected if there was a suspicion for $\geq$ T1a disease and the lesion was >15 mm (January 2017 to April 2023). This was compared with a conventional EMR predominant approach (CEA), where ESD was only performed in cases suspicious for deep submucosal invasion or T1b disease (February 2013 to December 2016). The primary outcome was curative oncologic resection (R0 resection with favorable histologic features).

Results: A total of 298 resections were performed in 298 patients (68 UEA, 230 SRAB). Median lesion size was 20 mm (IQR 15-30). T1a adenocarcinoma was identified in 83 (27.9%) and T1b in 58 (19.5%), of which 31 (10.4%) were SM1. Comparing T1a and T1b disease, the rate of enbloc resection (CEA 12 [46.2%] vs SRAB 103 [90.4%]; $P < 0.001$), R0 excision (CEA 7 [26.9%] vs SRAB 86 [74.8%]; $P < 0.001$) and curative resection (CEA 6 [23.1%] vs SRAB 58 [50.4%]; $P = 0.011$) was higher in the SRAB group. Among all T1a and T1b-SM1 cases with favorable histology, which underwent ESD, 39/46 (84.8%) were R0 excisions and are likely cured. There were no significant differences in adverse events ($P > 0.788$ for all).

Conclusion: A selective resection algorithm optimizes oncologic outcomes for Barrett's adenocarcinoma and mitigates the risk of piecemeal resection of cancers.

Introduction: Achieving Histologic Remission is a key therapeutic target in ulcerative colitis (UC) and is predictive of favourable clinical outcomes. Predicting consistent therapy responses in clinical trials and practice is an unmet need crucial for improving therapeutic decisions in UC patients.

Aims & Methods: Thus, our study aimed to develop a novel AI model for assessing histologic disease activity and predicting early therapy response in a Phase 2 Clinical trial UC cohort. We used 302 whole slide images (WSIs) from moderate-to-severe active UC patients enrolled in a phase 2 mirikizumab (anti-IL23 mAb) clinical trial to train a novel deep neural network (DNN) model for WSIs. 106 WSIs from baseline, 106 from 12 weeks of treatment and 90 from 52 weeks of treatment were included. The ability of the model to predict remission/activity and response to therapy at 12 and 52 weeks was assessed. The system output was compared with human assessment. Histologic remission was defined as Geboes <2.0 and histologic improvement as Geboes <3.0. An early response to therapy at different time points was based on histologic remission or histologic improvement.

Results: Using all available WSIs, the system distinguished histologic activity/remission with sensitivity, specificity, and accuracy of 89%, 86% and 88%, respectively. The DNN predicted response to therapy based on histologic remission with 79% sensitivity, 78% specificity, and 78% accuracy at week 12 and 80% sensitivity, 92% specificity, and 87% accuracy at week 52. Furthermore, the model predicted response to therapy based on histologic improvement with 79% sensitivity, 76% specificity, 77% accuracy at week 12 and 80% sensitivity, 92% specificity, and 87% accuracy at week 52.

	HR	Response to therapy			
		HR week 12	HR week 52	HI week 12	HI week 52
Sensitivity	88.5%	78.6%	79.5%	79.3%	79.5%
Specificity	86.4%	78%	92.2%	75.5%	92.2%
Accuracy	87.8%	78.3%	86.7%	77.4%	86.7%

Abbreviations: HI, histological improvement; HR, histological remission.

Conclusion: Our study shows the remarkable ability of this novel AI histology model to distinguish histologic remission and activity in a clinical trial cohort. Notably, the model accurately predicted response to therapy at weeks 12 and 52. This AI model represents a promising tool in clinical trials and potentially in practice, offering objective guidance for personalized management in UC patients.

SUBSTANCE P AND NK1R – A NOVEL NEUROIMMUNE PATHWAY IN GASTRO-OESOPHAGEAL REFLUX DISEASE

T. Leech¹, P. Woodland², D. Kellsell³, D. Blaydon³, M. Peiris⁴
¹Queen Mary University of London, Wingate Institute of Neurogastroenterology, London, United Kingdom, ²Queen Mary University Barts & the London, Wingate Institute of Neurogastroenterology, London, United Kingdom, ³Queen Mary University of London, Blizard Institute, London, United Kingdom, ⁴Blizard Institute, Queen Mary University of London, Centre for Neuroscience, Surgery and Trauma, Wingate Institute of Neurogastroenterology, London, United Kingdom

Contact E-Mail Address: t.leech@qmul.ac.uk

Introduction: Gastro-oesophageal reflux disease (GORD) is characterised by visceral pain hypersensitivity, manifesting as heartburn, and distal oesophageal inflammation. In the oesophageal mucosa of GORD patients, even without visible inflammation (non-erosive reflux disease; NERD) there is increased innervation of sensory nerve fibres containing Substance P (SP) (Xu et al., 2013). SP may be released in response to luminal refluxate or inflammatory mediators to potentiate neuro-immune pathways relevant to GORD pathogenesis. We aimed to investigate the contribution of SP and its receptor NK1R to GORD symptoms.

Aims & Methods: To assess expression of NK1R on native tissue epithelium, biopsies were collected from healthy controls (HC), functional heartburn (FH), NERD and erosive reflux disease (ERD) patients following informed consent (Royal London Hospital ethics number: 19/LO/1506) and prepared for immunohistochemistry. NK1R was co-stained with epithelial cell marker E-Cadherin, pan-leukocyte marker CD45, and general T lymphocyte marker CD3. NK1R protein level was determined by mean fluorescence intensity of 3 FOVs. Cells of the NE-1 oesophageal epithelial cell line were incubated with media containing 100 nM and 300 nM SP for 30 minutes. Cells were lysed and intracellular inflammatory pathway activation was determined by p-NF-κB/NF-κB ratio through Western blot. mRNA levels of the inflammatory cytokine CXCL8 were determined via qPCR with 18S rRNA as a housekeeping gene.

Results: Quantification of mucosal tissue samples showed NK1R mean fluorescence intensity was significantly higher in NERD (fold-change 1.52; $p<0.05$) and ERD (fold change 1.70; $p<0.01$) oesophageal mucosa compared to healthy control (n=6-8). Interestingly, NK1R was also found expressed in a sub-group of CD3+ T lymphocytes specifically in the papillae and epithelium of GORD patients. In NE-1 oesophageal epithelial cells, 30 minutes exposure to 100 nM (fold change 1.41; $p<0.05$) and 300 nM (fold change 1.92; $p<0.0001$) SP induced phosphorylation of NF-κB in a dose dependent manner (n=7-8). CXCL8 expression in NE-1 cells exposed to 30 nM, 100 nM, or 300 nM SP for 30 minutes resulted in significantly higher mRNA expression at the highest concentration (fold change 6.29; $p<0.05$), although a dose-dependent trend was observed at lower concentrations (n=3).

Conclusion: The significant increase in NK1R expression in NERD and ERD patients compared to healthy volunteers, combined with expression on T lymphocytes provides evidence, for the first time, that SP may have a critical role in potentiating pain sensation in the oesophagus. Indeed, SP directly induces NF-κB phosphorylation and increases transcription of inflammatory cytokine IL-8 in oesophageal epithelial cells. This demonstrates a novel neuroimmune pathway regulated by SP and NK1R that may be critical in GORD symptom generation.

Introduction: The recently developed Ulcerative Colitis Severity Index (UCSI) has been previously reported to be more accurate than the Mayo Clinic score to predict 1-year endoscopic improvement (EI) at baseline (defined as a Mayo endoscopic score ≤ 1) for patients with moderate-to-severe ulcerative colitis (UC), using data from the UNIFI ustekinumab phase 3 clinical trial.¹ Validation of the UCSI with additional therapies is needed to elucidate the potential of the UCSI to improve UC treatment by predicting long-term outcomes.

Aims & Methods: To further evaluate the utility of the UCSI as a predictive tool to determine EI, this study reports the predictive value of the UCSI using upadacitinib (UPA) phase 3 trial data in patients with moderate-to-severe UC (ClinicalTrials.gov identifier: NCT02819635).² This post-hoc analysis assessed the intention-to-treat population receiving UPA 45 mg once daily 8-week induction treatment and randomized to UPA 30 mg or UPA 15 mg in maintenance (n=444). Baseline UCSI scores for 409 participants (35 were missing data) were calculated as the sum of 6 subscores derived from prior biologic failure, albumin <40 g/L, C-reactive protein >5 mg/L, endoscopic erosions/ulcerations, histology structural/architectural changes, and Mayo stool frequency scores. Receiver Operating Characteristic (ROC) analysis was conducted for all specified efficacy endpoints. Area under the curve (AUC) and 95% confidence interval were calculated for 7 endpoints, including 1-year EI predicted by baseline UCSI and Mayo Clinic score. A nonparametric approach was used to compare AUC between UCSI and Mayo Clinic score, and to calculate p-values. The UCSI cut-off to predict 1-year EI was determined using the Youden index (defined as Youden = Sensitivity + Specificity - 1), which is the maximum potential effectiveness of a diagnostic or predictive test that maximizes the distance between the chance diagonal line and the point (x,y) on the ROC curve, a point farthest from random.

Likelihood of endoscopic improvement	Number of participants achieving EI out of total (%)	Sensitivity (95% CI)	Specificity (95% CI)	Positive predictive value (95% CI)	Negative predictive value (95% CI)	Positive likelihood ratio (95% CI)	Negative likelihood ratio (95% CI)
Low (UCSI score ≥ 10)	120/239 (50.2)	44 (37.8-51.1)	62 (54.8-68.5)	56.5 (49.0-63.9)	49.8 (43.5-56.1)	1.16 (0.9-1.5)	0.90 (0.8-1.1)
High (UCSI score <10)	96/170 (56.4)						

CI, confidence interval; EI, endoscopic improvement; ITT, intention-to-treat; MES, Mayo Endoscopic Score; OD, once daily; UCSI, Ulcerative Colitis Severity Index; UPA, upadacitinib.

*The ITT population (UPA 45 mg OD group) comprises participants who received UPA 45 mg OD 8-week induction treatment and who were enrolled under the protocol for the 52-week maintenance treatment period in Cohort 1 and randomized to UPA 30 mg or 15 mg OD.

Table. Accuracy of the UCSI for Prediction of 1-year Endoscopic Improvement (MES ≤ 1) in the ITT* Population, Based on a Threshold Score of 10.

Results: In AUC-ROC analyses of the UCSI and Mayo Clinic score to predict 1-year efficacy outcomes, the UCSI and Mayo Clinic score were similar (p-values ranging from 0.36 to 0.84). Both were considered poor with AUC-ROC ranging from 0.51 to 0.57. A cut-off point of 13 for UCSI based on the Youden index yielded low prediction capabilities. A cut-off of 10 was found in the initial derivation paper to dichotomize the likelihood of EI ('Low' as UCSI score ≥ 10 , 'High' as UCSI <10).¹ Using this cutpoint, there was again no difference in rates of EI (56.4% vs 50.2%, respectively) (Table).

Conclusion: The UCSI did not predict endoscopic outcomes when tested with this phase 3 dataset for UPA in UC, with UPA achieving EI regardless of the likelihood of achieving this outcome at 1 year, based on the UCSI threshold of 10. Further analysis with other datasets is needed to explore the predictive value of the UCSI for other therapies. The re-randomization study design might have affected the predictive value of the UCSI, and further analyses on treat-through studies are needed.

Introduction: Crohn's disease (CD) may manifest as perianal disease (PD) in up to 36% of cases. In the majority, PD occurs simultaneously or after the diagnosis of small bowel CD. Diagnosing CD in patients with isolated PD can be challenging. Small bowel capsule endoscopy (SBCE) has been shown to have a higher diagnostic yield for small bowel findings compatible with CD than other modalities.

Aims & Methods: This study aimed to assess the impact of SBCE as a diagnostic tool for CD in patients with isolated PD.

Retrospective cohort study spanning 2008 to 2023. Adult patients with isolated PD (recurrent fissures, trans-/supra-/extra-sphincteric fistula or abscess) and negative conventional workup for CD (ileocolonoscopy and cross-sectional imaging) who underwent SBCE (Pillcam, Given®) were included. Patients using nonsteroidal anti-inflammatory drugs or with a CD history were excluded. Demographics, biomarkers, SBCE findings and subsequent management were recorded and analyzed.

Results: Forty patients (mean age 40.2 years, 67.5% females) were included. SBCE identified findings compatible with small bowel CD (aphthous ulcerations, linear/circumferential ulcers and stenosis) in 32.5% (13 patients), enabling diagnosis and subsequent treatment in all of them, based on disease severity. In this group, mean previous fecal calprotectin (FC) was 722.2µg/g, but FC was inferior to 200µg/g in 46.2% (6 patients). In 4 patients (10%) with negative SBCE, isolated perianal CD was assumed and immunosuppressors were started. There was no statistically difference in FC of the patients with positive and negative SBCE. Laboratory findings (C-reactive protein, albumin), tobacco use and family history of CD/ulcerative colitis did not show significant associations with SBCE findings.

Conclusion: For patients with PD and a negative conventional CD workup, SBCE demonstrated a 32.5% incremental diagnostic yield, leading to therapy initiation based on severity.

Introduction: For patients living with inflammatory bowel diseases (IBD), the ultimate treatment goal is to live a "normal life." However, no validated patient-reported outcome measurement (PROM) exists yet to measure this. Moreover, most PROMs were developed by western healthcare professionals, lacking a global, patient-centred approach.

Aims & Methods: Through a world-wide patient-centred approach, we aimed to develop and validate a PROM that identifies and measures normality of life for patients with IBD, the "IBD LIFE."

IBD patients without an ostomy, pouch or significant other comorbidities could participate in the project. The development phase included 6-10 patients with Crohn's disease (CD) and 6-10 patients with ulcerative colitis (UC) from each of the participating countries (Argentina, Australia, India, the Netherlands, South-Korea and the USA).

The development phase consisted of (i) semi-structured qualitative interviews about living a normal life with IBD, (ii) an online Delphi round to rate item importance, (iii) a focus group to clarify wording, categorisation and scales, (iv) pilot-testing and (v) cross-cultural translation.

For the validation phase, 200 adult IBD patients are recruited per language (100 CD, 100 UC). At baseline (BL), we assessed clinical disease activity (using the Harvey Bradshaw Index (HBI) or Simple Clinical Colitis Activity Index (SCCAI)) and asked patients to complete a PROM set including the IBD LIFE, a general quality of life (QoL) PROM and an IBD-specific QoL PROM (Short-Form-36 (SF-36) and IBD Questionnaire (IBDQ)). In addition, 30 consecutive patients per language were asked to complete a second PROM set 2 weeks after baseline (W2), comprising of the IBD LIFE, IBDQ and question 2 from the IBD-control.

Internal consistency was assessed using Cronbach's α . Test-retest reliability was assessed through the intraclass correlation coefficient (ICC) by comparing IBD LIFE scores at BL and W2 in patients with stable QoL (de-

fined as <10% difference in the IBDQ score and the IBD control question 2 answered “no change”). Construct validity was assessed at BL through Spearman’s correlation coefficients between the IBD LIFE, the comparator QoL PROMs and disease activity indices.

Results: The IBD LIFE consists of 23 questions divided into 5 categories: physical items, activities, social items, psychological items and circumstances.

For the validation phase, we report on the first 364 included patients (200 Dutch, 100 Spanish and 64 English speaking patients, 187 UC and 177 CD, median disease duration 10 years [5-18], see table 1). In CD, median HBI was 2 [1-5] and in UC, median SCCAI was 1 [0-2]. PROM response percentage was 85%. 38 patients completed W2 visit, of whom 71% had stable QoL. The IBD LIFE showed excellent internal consistency (Cronbach’s $\alpha = 0.95$). Test-retest reliability was good (ICC = 0.94 [95% CI 0.88-0.98]). The IBD LIFE exhibited good construct validity, depicted by a strong correlation with IBD-specific QoL (IBDQ $r = 0.90$), and general QoL (SF-36 $r = 0.84$) and a moderate correlation with clinical disease activity (HBI $r = 0.58$; SCCAI $r = 0.54$).

	n = 364
Demographics	
Gender (male), n (%)	160 (41%)
Age (year), median [IQR]	41 [30-54]
Employment status (employed), n (%)	328 (90%)
Disease characteristics	
Diagnosis (CD), n (%)	177 (49%)
Median disease duration (year), median [IQR]	10 [5-18]
Naïve to advanced therapies, n (%)	215 (59%)

Introduction: Endoscopic confirmation of treatment response is recommended in ulcerative colitis (UC). However, colonoscopy (CS) is not well accepted by patients and approximately 50% of patients starting treatment do not undergo CS in the following 2 years. Fecal calprotectin (FC), a non-invasive biomarker of mucosal inflammation, is widely available, but a universal cut-off value applicable to all patients is not yet known.

Intestinal ultrasound (IUS) is emerging as an accurate tool for monitoring treatment response. In particular, the Milan ultrasound criteria (MUC) is a validated score to assess endoscopic activity in UC. $MUC \leq 6.2$ accurately detects Mayo endoscopic score (MES) ≤ 1 (REF 1 e 2).

Aims & Methods: The aim of this study was to evaluate the performance of non-invasive approaches in detecting treatment response in UC in an outpatient setting, using CS as reference standard.

All consecutive patients with UC seen in the outpatient clinic in one week and scheduled for a colonoscopy the following week were eligible. Treatment response was graded according to: a) symptoms (partial Mayo score, $PMS \leq 2$), b) biomarkers ($FC \leq 250$ mcg/g and C-reactive protein, $CRP \leq 5$ mg/L), c) Milan Ultrasound Criteria ($MUC \leq 6.2$) and d) combined approach with MUC and FC ($MUC \leq 6.2 + FC \leq 50$ mcg/g or $MUC \leq 6.2 + FC \geq 50 \leq 250$ mcg/g). Receiver Operating Characteristic (ROC) curve analysis was used to compare the non-invasive approaches, using Mayo endoscopic score as reference standard (response defined by $MES \leq 1$).

Results: 97 patients with UC were enrolled (60 males, median age 39 years). 77 patients were in biologics or small molecules, 29 in steroids and 5 in immunosuppressants. Response to treatment (defined by $MES \leq 1$) was correctly identified in 64% of cases based on symptoms, 68% using biomarkers, 80% using MUC, and 83% with a combined approach. Biomarkers-based detection was not superior to symptoms (0.695 vs. 0.671; $p = 0.74$). Ultrasound-based detection was superior to both symptoms (0.822 vs 0.671; $p = 0.015$) and biomarkers (0.822 vs 0.695; $p = 0.046$). Combined approach was superior to symptoms (0.825 vs 0.671; $p = 0.016$) and biomarkers (0.825 vs 0.695; $p = 0.004$), but not to IUS (0.825 vs 0.822; $p = 0.943$).

Conclusion: The use of an ultrasound-based approach in combination with FC increases our ability to assess treatment response in UC patients in real time, possibly avoiding CS.

Introduction: Data on Intestinal Ultrasonography (IUS) in ulcerative colitis (UC) are growing especially in monitoring colonic lesions after therapies. Ultrasonographic parameters derived from studies in Crohn's disease populations.

Aims & Methods: Aim of our multicenter study was to define IUS parameters of normality and activity in UC patients compared to a healthy control group (HC). Secondary aim was to evaluate severity of colonic lesions using endoscopy as reference standard.

From July 2022 to Oct. 2023, we conducted a multicenter study at 6 IBD centers. Patients (pts) with UC and indication to perform colonoscopy were longitudinally enrolled. HC [no gastrointestinal symptoms, no anemia and normal fecal calprotectin (FC)] were enrolled to establish normal values. The analysis was performed per patient and per segment evaluating colonic wall thickening (CWT), colonic wall flow, Milan Ultrasound Criteria (MUC), Mayo endoscopic score (MES) and partial/full Mayo score. The sample size for UC cohort and HC, the area under (a ROC) curve, Spearman's correlation among clinical data, FC, IUS and endoscopy were calculated.

Results: 180 UC patients and 80 HC were enrolled. In the UC cohort, 53% were male with a median age of 40 years (range 18–78), 64% had extensive colitis and 36% had left colitis. In the HC, 44% were male with a median age of 29 years (range 19–70). Median CWT in comparison to MES in UC patients and median CWT in HC were shown in Table 1. Rectum wall thickening showed higher values than other colonic segments. A $CWT \geq 2.75$ mm showed a sensitivity, specificity, NPV and PPV of 54%, 96%, 48% and 97%, respectively, in differentiating UC patients from HC [AUC=0.72]. A rectum wall thickening >4.55 mm showed a sensitivity, specificity, NPV and PPV of 67%, 84%, 56% and 89%, respectively, in differentiating UC patients from HC [AUC=0.82]. A $CWT \geq 3.5$ mm showed a sensitivity, specificity, NPV and PPV of 57.4%, 94.3%, 86% and 78%, respectively, in differentiating activity from remission in UC patients [AUC=0.84]. A rectum wall thickening >5 mm showed a sensitivity, specificity, NPV and PPV of 57.5%, 85.7%, 41% and 92%, respectively, in differentiating UC rectal activity from remission [AUC=0.81]. The correlation of the CWT or MUC vs MES was better than clinical data and FC.

Conclusion:

	CWT mm median; (range)			
	Right colon	Transverse colon	Left colon	Rectum
Healthy control N=80	1.9; (1.2-3.4)	1.8; (1.3-5)	2; (1.3-3)	3.8; (1.5-5.5) [§]
MES 0 N=36	2.3; (1.1-4)	2.25; (1.4-4.2) [°]	3; (1.5-4.2)	4; (3-6) [*]
MES 1 N=32	1.65; (0.9-3.8)	1.7; (1.2-3.2) [°]	2.6; (1.5-6)	4.95; (1.9-8) [*]
MES 2 N=45	2.1; (1-4)	2.3; (1.3-5.7) [°]	3.5; (1.3-5.5)	5.15; (3-10) [*]
MES 3 N=67	3; (1-7)	3; (1.3-7) [°]	5.3; (2.7-8.5)	5.5; (3.2-9.7) [*]

[§]Data available in 25 pts, [°]Data available in 108 pts, ^{*}Data available in 178 pts

IUS, importantly CWT as the most relevant parameter, is highly accurate to diagnose and detect activity in UC patients.

Introduction: Ulcerative Colitis (UC) diagnosis relies on invasive endoscopic biopsy collection for histological assessment. There is a critical need for specific, easy-to-detect and non-invasive approaches to assessing disease activity such as liquid biopsy. Extracellular vesicles (EVs) carrying tissue-specific miRNAs are a promising means of liquid biopsy for

detection in blood. However, the low detectability of these EV-derived miRNAs hinders their clinical application. Low-intensity pulsed ultrasound (LIPUS) has the potential to modulate EV biogenesis and enhance their release carrying UC-specific miRNAs.

Aims & Methods: We explored Low-intensity Pulsed Ultrasound (LIPUS) technology to boost the release of mucosal miRNAs carried by extracellular vesicles (EVs) as UC biomarkers, potentially enabling disease activity monitoring through a blood test.

We conducted a simulation framework to estimate the optimal energy dosage, *in-vitro* defined, reaching the colon *in-vivo*. LIPUS stimulation was performed during the active and recovery phase of acute and chronic colitis models. Murine models of colitis were obtained by dextran sodium sulfate (DSS) administration to C57BL/6 female mice, whilst DSS cycles were stopped for recovery. Four and 35 UC patients were enrolled for *ex-vivo* gut biopsy stimulation and for blood collection respectively, stratified by disease activity defined by endoscopic mayo (e-Mayo) score. EV-miRNA isolated were profiled by next-generation sequencing and microarray.

Results: Our study demonstrates that LIPUS at 38 kHz, 150 mW/cm² for 180s effectively promotes miRNA release reflecting the chronic and acute inflammatory status of mucosa in experimental colitis models. *Ex-vi-vo* LIPUS stimulation of UC patient gut biopsies not only confirmed the association of murine miRNAs with disease activity in humans, but also enhanced additional 19 miRNAs, displaying their potential main role in the mucosal inflammatory process. Remarkably, the validation in a large cohort of UC patients' blood corroborated LIPUS-induced miR-532-3p to solely correlate with disease severity, while other miRNAs were either highly variable or undetectable without LIPUS stimulation.

Conclusion: Therefore, LIPUS is a safe, non-invasive method to enhance the detection of rare biomarkers in blood, potentially paving the way for a new era of gut liquid biopsy for monitoring UC disease progression.

Introduction: A major difficulty in treating Crohn's disease (CD) lies in the unreliable association between clinical symptoms and underlying inflammation, hindering effective monitoring. Intestinal ultrasound (IUS) has emerged as a valuable, non-invasive, and well tolerated tool for assessing inflammatory activity in CD. The "Selecting Therapeutic Targets in Inflammatory Bowel Disease" (STRIDE-II) guidelines recognize the transformative impact of IUS in inflammation assessment but hesitate to endorse transmural healing as a primary treatment target due to current limitations of available therapies in achieving this outcome. However, limited data exist on the applicability of IUS in patients with newly diagnosed CD who might not have developed irreversible fibrotic alterations.

Aims & Methods: The primary aim of this study was to characterize the sonographic features of CD at diagnosis and throughout the initial year post-diagnosis. Additionally, we sought to assess the predictive capability of IUS herein.

We conducted a prospective, population-based cohort study involving newly diagnosed patients with CD. Patients were systematically monitored using IUS in tandem with symptomatic, biochemical, and endoscopic evaluations throughout the first year following diagnosis. Transmural remission (TR) was defined as BWT $\leq$ 3 mm without colour Doppler signal, and symptomatic remission as Harvey-Bradshaw Index $\leq$ 4.

Results: During the study period (May 2021 – May 2023), 201 patients with adult-onset CD were included. No significant associations were observed between sonographic characteristics of inflammation and diagnostic delay.

At three months post-diagnosis, TR was achieved in 38% of patients, with a higher proportion observed in those with colonic disease (L1: 33%, L2: 52%, L3: 27%; $p = 0.05$). TR at three months was significantly associated with symptomatic remission at subsequent follow-ups during the first year (3 months: 87% vs. 51%, $p < 0.001$; 6 months: 87% vs. 61%, $p = 0.004$; 9 months: 76% vs. 49%, $p = 0.012$; 12 months: 87% vs. 64%, $p = 0.013$), as well as a reduced risk of treatment escalation (20% vs. 65%, $p < 0.0001$) during this period.

By 12-month, 41% of patients achieved TR, with no significant association observed with disease location. In a multivariable analysis adjusted for age, sex, smoking, disease location, and baseline sonographic inflammation, a higher body mass index (BMI) significantly decreased the likelihood of achieving transmural remission (overweight: Odds ratio (OR) = 0.13, 95% confidence interval (CI): 0.02–0.93; obesity: OR = 0.06, 95% CI: 0.01–0.64).

Among the 126 patients with ileal or ileocolonic disease, 16 (13%) underwent ileocecal resection (ICR) within the first year. In an analysis of receiver operating characteristic area under the curve (ROC AUC), which included endoscopic, symptomatic, sonographic, and biochemical findings, the

International Bowel Ultrasound Segmental Activity Score (IBUS-SAS) in the terminal ileum at diagnosis emerged as the most accurate predictor of ICR during this period: IBUS-SAS 63 (AUC = 0.92, sensitivity = 100%, specificity = 73%).

Conclusion: The findings of this study highlight TR as an attainable goal for newly diagnosed CD patients with a positive impact on the disease course. Moreover, the negative influence of high BMI on the likelihood of achieving TR underscores the necessity for further investigation into the impact of weight on the disease course of IBD. The study also reveals that sonographic inflammation in the terminal ileum at diagnosis is the most accurate predictor of the need of ICR within the first year.

Introduction: Virtual Chromoendoscopy (VCE) has proven effective in predicting disease activity in Ulcerative Colitis (UC), although challenges persist regarding local availability and expertise. Artificial intelligence (AI) models applied to VCE have demonstrated a remarkable ability to rapidly, objectively, and accurately predict inflammation. Nonetheless, training machine algorithms across different enhancement modalities remains challenging. Hence, this study pioneers a novel machine model designed to simultaneously detect different VCE enhancement modalities and facilitate the transition between images to improve and standardise AI-based assessment of inflammation in UC.

Aims & Methods: Endoscopic videos from 302 UC patients recruited in the international real-life prospective PICaSSO study were analysed. The endoscopic assessment of the rectum and sigmoid colon was performed using white-light endoscopy (WLE), iScan 2 and iScan 3 modalities (Pentax, Japan). In the study's first phase, a switching AI model that detects and converts images across different modalities was developed. A neural network (NN) to identify the acquisition modality of each frame was trained and tested with 1531 (510 WLE, 518 iScan 2, and 503 iScan 3) and 321 (103 WLE, 109 iScan 2, 109 iScan 3) randomly extracted frames, respectively. Subsequently, a CycleGAN model was trained with 900 images per modality to allow inter-modality image switching. In the second phase, 240 annotated videos (4605 frames) were selected, with endoscopic activity assessed by experts using the UC Endoscopic Index of Severity (UCEIS) for WLE and the Paddington International Virtual Chromoendoscopy Score (PICaSSO) for VCE. Videos were switched to missing modalities and used to train a previously developed deep-learning model for inflammation assessment.¹ Four models were trained: three using a single modality as

input and one combining all modalities. Model performance in predicting inflammation was evaluated by computing accuracy, sensibility, specificity and AUC.

Results: The switching model showed a remarkable ability to classify and convert images across different endoscopic modalities, achieving a 92% NN classifier accuracy on the test set. The deep learning model showed a sensitivity of 80% (95% CI 59%-93%), specificity of 94% (95% CI 82%-99%), accuracy of 89% (95% CI 79%-95%) and AUC of 0.91 in predicting inflammation when combining images obtained through the switching model. This multimodal approach improved the performance of single-modality models.

Conclusion: This study introduces an innovative multimodal "AI-switching" model capable of accurately detecting and simultaneously switching between different endoscopic enhancement modalities. Combining the images obtained through this model enables precise assessment of inflammation in UC patients, exhibiting promising potential for application in clinical trials and clinical practice.

Modality	Accuracy, % (95% CI)	Sensitivity, % (95% CI)	Specificity, % (95% CI)	AUC
Unimodal - WLE	82 (71-90)	81 (54-96)	82 (70-91)	0.84
Unimodal - iSCAN2	82 (71-90)	71 (49-87)	88 (75-95)	0.86
Unimodal - iSCAN3	82 (71-90)	73 (50-89)	86 (73-94)	0.88
Unimodal - WLE + iScan2 + iScan3	89 (79-95)	80 (59-93)	94 (82-99)	0.91

Introduction: Histopathological analysis of mucosal biopsies in ulcerative colitis (UC) is currently performed by pathologists on digital whole slide images (WSIs) or under the microscope; but established grading scales are not routinely employed and are subject to well-described intra- and inter-observer variations. Previously, we demonstrated that our Artificial Intelligence (AI) Tool can assign a Nancy Index (NI) [1] to a biopsy case with accuracy comparable to an expert pathologist [2].

Here we introduce the novel concepts of "smart tiling" and HeatMaps for comprehensive AI-powered assessment of WSIs and deploy these to describe a sample of WSIs.

Aims & Methods: We refer to a high-power location in a WSI as a 'tile', a fixed size region of interest of 1024 by 1024 pixels, with 0.5 microns per pixel in WSI with 20-fold magnification. Our previously validated AI Tool identifies tissue types, cell types (neutrophils, lymphocytes, plasmacytes), cell

density, crypts, and ulcerations, and calculates an NI with high degree of agreement [2]. In this analysis, we 'mapped' the WSIs on a tile-by-tile basis and using the NIs, created a HeatMap of grades from NI 0 to 4. The NI for the WSI was selected on the basis of the most frequently appearing NI. We included fixed size tiles that contained more than 15% of tissue in them and excluded the rest. In this feasibility study, we processed 11 WSIs received from 2 different scanners, which resulted in a 1175 tile database.

Results: The average number of tiles per WSI was 107, with a range from 30 tiles (WSI with NI=0) to 203 tiles (WSI with NI=4). Every WSI contained multiple tiles with a variety of NIs. WSIs scored as NI= 3 or 4 contained on average 53 tiles of NI=4, 36 with NI=3, 16 with NI=2, and 8 with NI=1 and 8 with NI=0. WSIs scored as NI= 0-2 contained on average 16 tiles of NI=4, 5 with NI=3, 34 with NI=2, and 10 with NI=1 and 18 with NI=0. The average neutrophil or eosinophil / lymphocyte / plasmacyte counts per tile were: in WSIs with NI=0 15/22/52, in WSIs with NI=2 22/35/88, in WSI with NI=3 57/53/125, in WSI with NI=4 73/31/85. The average sum of neutrophils divided by the number of tiles in WSIs with NI=0 0.83, in WSIs with NI=2 1.92, in WSI with NI=3 20.3, in WSI with NI=4 25.6.

Conclusion: This is the first description of novel concepts for histopathological analysis of mucosal biopsies in UC with smart tiling and HeatMaps. We identified significant heterogeneity and variation among tiles and within WSIs in both degree of inflammation by the AI-determined NI, but also in cell types. These novel findings and automatic assessments provide new insight into the pathophysiology of UC and may allow for more reliable clinical assessments in our patients.

Introduction: Over the past few years, the incidence of Ulcerative Colitis (UC) has been increasing worldwide. In the clinical management of UC, assessing its severity based on disease activity and extension is particularly relevant, as it allows for the differentiation of patients into various groups and facilitates therapeutic optimization. Therefore, the development of an Artificial Intelligence (AI) platform capable of identifying UC extension and activity from hospital clinical notes significantly aids gastroenterologists in their daily healthcare practices and supports hospital research endeavors.

Aims & Methods: We aimed to assess the accuracy of an integrated AI software platform in evaluating the colonic extent and endoscopic activity of UC using unstructured data from hospital medical records.

A model based on natural language processing and keyword-based extraction was developed for determining the extent and activity of UC. For algorithm development, training, validation, and testing, clinical records from 465 patients diagnosed with UC at a university-affiliated hospital between January 2005 and February 2023 were utilized.

Results: A total of 556 episodes from 16 patients (31.3% men; median age 47 ± 21.5 years) were used to test the model. Concerning the colonic extension, the model demonstrated an accuracy of 0.99, precision of 0.93, recall of 0.90, and F1 score of 0.92. Regarding endoscopic activity, the model achieved an accuracy of 0.95, precision of 0.89, recall of 0.91, and F1 score of 0.90.

Conclusion: The AI platform effectively identified the extent and endoscopic activity of UC within unstructured data from hospital medical reports. The algorithm demonstrated promising results, with high accuracy and excellent performance metrics in the variables studied, positioning it as a potential candidate for future clinical applications.

Introduction: Metastasis is the major cause of mortality among colorectal cancer (CRC) patients and represents a crucial cancer research challenge. Metastasis is the results of an intimate crosstalk between cancer cells and the surrounding tumor microenvironment, where neoplastic cells exploit the inefficient and leaky tumor vessels to disseminate to secondary organs¹. In this context, the extracellular matrix protein Multimerin-2, specifically deposited by endothelial cells (EC), is instrumental for the maintenance of vascular homeostasis, ensuring the proper formation of cell-cell junctions via the VEGFR2 signaling².

Aims & Methods: We observed that Multimerin-2 is down modulated in tumors both at transcriptional and post-translational levels. Thus we hypothesized that Multimerin-2-devoid vessels may enhance cancer cell dissemination, being characterized by a compromised endothelial barrier. Multimerin-2 expression was analyzed in human CRC samples through IHC, ELISA and *in silico* by the tnmplot.com tool. The effects of Multimerin-2 loss were assessed *in vitro* through transmigration assays upon Multimerin-2 down-regulation in EC cells and the molecular mechanism verified by WB and qRT-PCR. The putative Multimerin-2-affected metastatic dissemination was assessed through intravenous injection of MC38 colon cancer cells in *wt* and *Multimerin-2*^{-/-} mice.

Results: Multimerin-2 expression is significantly reduced within the tumor tissue respect to the normal counterpart among CRC patients, despite at variable degree. Importantly, *in vitro*, we found an increased number of CRC cells transmigrating through a Multimerin-2-depleted endothelium. This phenomenon was not VEGFR2-dependent since the use of a VEGFA blocking agents did not affect the extravasation of tumor cells. Indeed, under tumor-mimicking conditions, the knock-down of Multimerin-2 in ECs induces the upregulation of the vascular adhesion molecule VCAM1, a molecule exploited also by cancer cells to transpass the endothelium³. Accordingly, the intravenous injection of B16F10 syngeneic melanoma cells, as well as MC38 colon cancer cells, in *Multimerin-2*^{-/-} mice led to the formation of a higher number of metastatic lesions in the lungs.

Conclusion: Overall, these data indicate that Multimerin-2 expression is required to maintain vascular stability and halt the escape of cancer cells, suggesting that the Multimerin-2-devoid tumor vessels may represent a preferential route for metastatic dissemination, during CRC progression.

Introduction: The American Gastroenterological Association has recommended metformin as chemopreventive agent for colorectal cancer (CRC).

Aims & Methods: We aimed to compare sodium-glucose cotransporter-2 inhibitors (SGLT-2i) (either as monotherapy or combination therapy with metformin) to metformin monotherapy on CRC risk in type 2 diabetes (T2D) patients.

Using the territory-wide electronic healthcare database in Hong Kong, we identified all adults with T2D aged ≥ 18 years initially receiving SGLT-2i or metformin between January 2015 and June 2022. Index date was defined as the first date of study medication prescription and a 180-day lead-in period was used to categorize patients into SGLT-2i(+)/metformin(-), SGLT-2i(+)/metformin(+), and SGLT-2i(-)/metformin(+) groups. Primary outcome was CRC development. Secondary outcomes were (i) CRC-related mortality, (ii) colonic adenoma (any, non-advanced and advanced) development. Advanced adenoma was defined as adenoma with villous histology or high-grade dysplasia. Overlap weighting was applied to balance baseline characteristics, including age, sex, body mass index, smoking, alcohol, hemoglobin A1c, T2D duration, comorbidities (dyslipidemia, hypertension, stroke, heart failure, coronary artery disease, atrial fibrillation), prior colonoscopy, other anti-diabetic medications, aspirin, and statins. The intention-to-treat design was applied, and multivariable Cox regression models were conducted to estimate adjusted hazard ratios (aHRs) of outcomes with SGLT-2i use. Dose-response relationship was investigated according to defined daily dose (DDD), with one DDD being equivalent to daily use of dapagliflozin 10 mg, canagliflozin 200 mg, empagliflozin 17.5 mg, or ertugliflozin 10 mg. Duration-response relationship was investigated according to the proportion of SGLT-2i use, derived by dividing the treatment duration by follow-up duration.

Results: Among 436,890 T2D patients (mean [SD] age: 64.3 [11.6] years; 48.7% male), there were 8,481 (1.9%) SGLT-2i(+)/metformin(-), 48,008 (11.0%) SGLT-2i(+)/metformin(+), and 380,401 (87.1%) SGLT-2i(-)/metformin(+) users. During a median follow-up of 6.3 years [interquartile range: 3.2–7.8], there were 4,976 (1.1%) incident CRC cases and 1,311 (0.3%) CRC-related deaths. When compared with SGLT-2i(-)/metformin(+), both SGLT-2i(+)/metformin(+) and SGLT-2i(+)/metformin(-) were associated with a lower CRC risk (aHR:0.51, 95%CI:0.36-0.73; and aHR:0.46, 95%CI:0.25-0.86, respectively). There was no difference in CRC risk between SGLT-2i(+)/metformin(+) and SGLT-2i(+)/metformin(-) (aHR:1.11, 95%CI:0.54-2.26). When metformin was used as the reference group, a stepwise decreasing risk of CRC was observed for SGLT-2i 0.5-0.9 DDD (aHR:0.76, 95%CI:0.64-0.90) and 1 DDD or above (aHR:0.46, 95%CI:0.35-0.60) ($P_{\text{trend}} < 0.001$). Similarly, a duration-response relationship existed – SGLT-2i use proportion $< 80\%$ with aHR:0.73 (95%CI:0.57-0.94) and $\geq 80\%$ with aHR:0.62 (95%CI:0.52-0.74) ($P_{\text{trend}} < 0.001$). In addition, SGLT-2i was associated with lower risk of CRC-related mortality (aHR:0.45, 95%CI:0.29-0.68), any adenoma (aHR:0.81, 95%CI:0.75-0.88), non-advanced adenoma (aHR:0.84, 95%CI:0.77-0.91) and advanced adenoma (aHR:0.59, 95%CI:0.48-0.72) than metformin monotherapy.

Conclusion: SGLT-2i, either as monotherapy or combination therapy with metformin, associated with lower risk of CRC than metformin monotherapy, in a dose- and duration-response manner. Randomized clinical trials

investigating effect of SGLT-2i on colonic polyp are warranted to validate our study findings.

Introduction: Colorectal cancer (CRC) is the third-most common malignancy worldwide. Lysyl oxidase-like protein 2 (LOXL2), which promotes crosslinking of collagen and elastin, contributes to tumor progression in different tumour entities, but its role in CRC has not been evaluated. Here, we unraveled the role of LOXL2 in regulating tumour immune microenvironment of CRC and identified LOXL2 as a potential target for immunotherapy.

Aims & Methods: We analyzed the expression of LOXL2 in the Cancer Genome Atlas (TCGA) data. The effect of LOXL2 on CRC cell growth was determined by cell viability and colony formation assays. In vivo models were established by subcutaneous injection of colorectal cancer cell lines into immunodeficient NOD-SCID- γ (NSG) mice and immunocompetent wild-type BALB/c mice. Flow cytometry and immunohistochemistry were used to analyze immune cell composition. The collagen fibers in the extracellular matrix (ECM) were observed by masson staining, second harmonic generation imaging (SHG), and two-photon fluorescence imaging.

Results: Survival prognosis analysis revealed that high LOXL2 expression was correlated with poor survival of patients with CRC in TCGA cohort. However, we found that LOXL2 overexpression in human (HCT116 and DLD1) and mouse (CT26 and MC38) CRC cell lines had little effect on tumor growth *in vitro* and in immunodeficient mice. But its overexpression in mouse CRC cell lines could significantly promote tumor growth in immunocompetent mice ($p < 0.05$). Overexpression of LOXL2 led to CXCL1 upregulation in the supernatant of CRC cells and CRC tumor tissues; subsequently, upregulation of CXCL1 induced more migration of myeloid-derived suppressor cells (MDSCs) *in vitro* and recruited more MDSCs in the tumor microenvironment. On the other hand, LOXL2 increased the crosslinking of collagen fibers *in vitro* and in the tumor microenvironment, which subsequently activated the function of MDSCs (up-expression of Arg1, IDO1, and INOS) and increased the oncostatin M (OSM) secreted by MDSCs. In turn, OSM secreted by MDSCs induced the expression of LOXL2 in CRC cells. The accumulation and activation of MDSCs in the tumor microenvironment inhibited the infiltration and function of CD8⁺ T cells, which suppressed the anti-tumour immunity of the host. Targeting of LOXL2 with a neutralizing antibody or inhibitor (PAT-1251) significantly impaired tumor growth ($p < 0.05$) and MDSC infiltration and activation ($p < 0.05$) in immunodeficient mice. Finally, PAT-1251 boosted anti-PD1 efficacy in colorectal cancer, suggesting that it could be repurposed to improve immunotherapy efficacy.

Conclusion: Our findings revealed that LOXL2 exerted a pro-tumorigenic role in CRC. LOXL2 recruited and activated MDSCs through CXCL1 and

crosslinking of collagen fibers, respectively, subsequently reducing infiltration and activation of anti-tumor CD8⁺ T cells in the tumor microenvironment. Targeting this axis with PAT-1251 improved the efficacy of immunotherapy in colorectal cancer.

Introduction: Tumor angiogenesis is considered as a hallmark of cancer¹ and plays a critical role in colorectal cancer (CRC) development and progression^{2,3}. Tumor vasculature promotes tumor growth and metastasis since it not only provides nutrients and oxygen for the rapid proliferation of cancer cells as well as a route for metastatization, but also affects the infiltration of immune cells to the tumor site. Thus, the targeting of angiogenesis has become an attractive strategy against various human malignancies, including CRC⁴. In fact, tumor-associated vessels are leaky and poorly efficient due to the dismantlement of the basement membrane and the loss of pericytes, thus preventing proficient drug delivery to the tumor⁵. In this context, we demonstrated that Multimerin-2, an extracellular matrix glycoprotein deposited along the blood vessels in juxtaposition between endothelial cells and pericytes, mural cells fundamental in vessels stabilization, is key in the maintenance of vascular homeostasis⁶. However, the effects of this molecule on pericytes biology and its putative impact on the immune cells' recruitment are still poorly understood. Since, many vessels associated with CRC lose Multimerin-2 expression, thus we aimed at verifying the effects of this loss in pericyte recruitment, vascular stability, and the surrounding tumor microenvironment.

Aims & Methods: Immunohistochemistry analysis on colorectal cancer patients' biopsies revealed that colon cancer associated vessels display a downregulated expression of Multimerin-2. Thus, we aimed at verifying the extent of pericyte recruitment by Multimerin-2-devoid vessels in a colon cancer model and at evaluating how Multimerin-2 loss affects the surrounding tumor microenvironment. Human umbilical vein endothelial cells (HUVEC) and Human brain vascular pericytes (HBVP) were used as *in vitro* models for proliferation, functional assays, transcriptomic and proteomics analyses. Wild type and *Multimerin-2*^{-/-} C57BL/6 mice were subcutaneously injected with the syngeneic colon cancer MC-38 cells and pericyte coverage and microenvironmental features were assessed in tumor sections by immunofluorescence as well as drug delivery following cisplatin treatment six hours prior sacrifice.

Results: We demonstrated that Multimerin-2 promotes pericytes migration, adhesion, and proliferation. Consistently, MC-38 xenografts from Multimerin-2 mice displayed a decreased pericytes coverage along the vessels as well as increased intratumoral hypoxia, suggestive of vascular inefficiency. In fact, upon treatments we counted less DNA \cisplatin adducts in tumors from *Multimerin-2*^{-/-} mice. Interestingly, tumors from Multimerin-2 mice also displayed an altered CD68 cells infiltrate, suggesting that Multimerin-2 loss can affect macrophages recruitment to the tumor

site. Accordingly, a higher number of the monocytic-like cells THP-1 migrated through a Multimerin-2-depleted endothelium. Furthermore, we observed that the loss of Multimerin-2 also associates with the expression of cytokines involved in macrophages recruitment.

Conclusion: These results suggest that Multimerin-2 loss impairs the pericyte recruitment, adhesion and proliferation. As a result, the vasculature lacking Multimerin-2 is utterly destabilized leading to increased intratumoral hypoxia and poorly efficient drug delivery. Importantly, the absence of Multimerin-2 also impairs the immune response suggesting that different Multimerin-2 expression in CRC tumor associated vessels could represent a promising biomarker to predict the efficacy of chemotherapy and/or immune therapy in CRC patient treatment

Introduction: T cells, are a major regulator and source of pro-inflammatory cytokines, which may promote colitis, but be protective in some cancers^{1,2}. Nevertheless, limited efforts have been made to explore factors which determine the phenotype of T cells and their impact on the above-mentioned phenomena. The adhesion G protein-coupled receptor F5 (ADGRF5) belongs to seven-transmembrane receptor subfamily and may be related to development of some cancer types³.

Aims & Methods: The aim of the study was to assess the significance of ADGRF5 for T cell function and its impact on colitis and colon cancer progression. WT and ADGRF5 knockout CD4⁺ T cells were examined for cytokine genes and proteins using real-time PCR, Western blot and multiplex analysis. Tumor killing assay and flow cytometry analysis were performed to evaluate tumor killing properties of T cells co-cultured with MC38 colon cancer cells. ADGRF5 WT and KO mice were utilized to examine the impact of ADGRF5 on colitis, colitis-associated cancer development and colon

cancer growth. Adoptive transfer of WT and ADGRF5 knockout CD4⁺ and CD8⁺ T cells were examined in tumor models to assess their role in disease progression.

Results: In murine model of colon cancer, animals with ADGRF5 knockout developed significantly smaller tumors which was accompanied by enhanced CD3 expression and hyperproduction of cytokines related to T cell action compared to wild type mice. *Ex vivo* analysis of two main population of T cells obtained from spleen of wild type and ADGRF5 knockout mice revealed that activated CD4⁺ but not CD8⁺ T cells with ADGRF5 were manifested by increased production of major anti-cancer molecules such as interferon γ (IFN- γ), perforin and granzyme B, and were characterized by secretion profile of cytokines related to mixed phenotype of T helper (T_H) 1 and T_H2 cells. Moreover, we documented higher proportion of apoptotic cells in co-culture of MC38 colon cancer cells with ADGRF5 knockout but not wild type CD4⁺ T cells. Finally, in the murine model of colon cancer adoptive transfer of CD4⁺ T cells with ADGRF5 knockout led to a significant reduction of tumor volume which was reversed by administration of antibody against IFN- γ . Nevertheless, ADGRF5 knockout in mice with colitis-associated colorectal cancer and colitis was related to significantly higher number of colon tumors and worse disease activity index compared to wild type animals, respectively. These results together with the analysis of gene expression signature in inflamed colons suggest opposite role for ADGRF5 in colitis than in the allograft colon cancer.

Conclusion: ADGRF5 is a critical regulator of T cell function and specific knockout of ADGRF5 reprograms CD4⁺ T cells into the pro-inflammatory phenotype. Our *in vitro* and *in vivo* studies indicated that ADGRF5 knockout in T cells promote pro-inflammatory cytokines, which prevent gastrointestinal cancer progression while boost both colitis and colitis-associated colorectal cancer development.

A DYNAMIC MOLECULAR LANDSCAPE AT SINGLE-CELL RESOLUTION AND THE IMPORTANCE OF LIGAND-RECEPTOR GENES THROUGH THE PROGRESSION OF COLORECTAL CANCER

J. Sheng¹, N. Li², Y. Liao¹, Y. Zhang¹, H. Chen¹, M. Tu¹, G. Zhong¹, C. Xiong¹, Z. He¹, Y. Lei², P. Zheng², L. Wang³, X. Gao³, Y. Zhu², J. Liu², H. Fan¹

Introduction: As common precursors to colorectal cancer (CRC), polyps and adenomas in the large intestine may develop into malignancy over time through a cascade known as the "normal-polyp-adenoma-carcinoma" sequence. Colorectal cancer (CRC) is the third most common cancer and the leading cause of cancer-related death worldwide, with an estimated increase to 3.2million new cases and 1.6million deaths by 2040

. The high mortality of CRC is largely due to the late diagnosis, incomplete molecular understanding of pathological progression, and limited treatment options for patients with advanced disease stage. Therefore, the identification of novel biomarkers at early (pre-cancerous) phase, thorough elucidation of pathological mechanisms, and development of effective therapies is crucial for CRC diagnosis and treatment.

Aims & Methods: Here we have utilized 10x genomics scRNA-seq platform to perform a high-resolution transcriptomic analysis of three normal colorectal tissues, two samples with inflammatory polyps, two specimens with adenomatous polyps and three CRC samples.

Results: By analyzing the scRNA-seq data of the ten human colorectal samples, which represent the four phases of colorectal pathogenesis, in combination with validation by immunofluorescence staining using expanded clinical samples, and together with verification using large scale TCGA and Kaplan-Meier data, we revealed a dynamic molecular landscape and for the first time demonstrated the importance of ligand-receptor genes, transcription factors and genes encoding multiple immunoglobulins and heat shock proteins driving the colorectal carcinogenesis.

Besides the heterogeneity of (sub-) cell types and difference of the transcriptomic profiling across the four stages, one of the most interesting and novel findings of this study is that the expression of ligand-receptor genes can be used to determine the cell types and even cell sub-types, at least for the colorectal tissues collected in this study, not the expressions of other gene sets, such as cell surface receptor signaling pathways, cell-cell signaling, transcription factors, cytokines, cell activation factors, cell signaling factors, or extracellular matrix, implying that ligand-receptor pairs are fundamentally important for the cell type determination and cell-cell communications in colorectal tissues.

We found that some genes encoding immunoglobulin members are highly expressed in the T cells (*IGHA1*, *IGHA2*, *IGKC* and *IGLC2*) and in the fibroblasts (*IGHA1*, *IGHA2*, *IGLC1*, *IGLC2*, *IGKC* and *JCHAIN*) from normal colorectal tissues, while some genes encoding heat shock proteins are highly expressed in T cells (*HSP90AA1*, *HSP90AB1*, *HSPA1B*, *HSPD1*, *HSPE1* and *HSPH1*) and plasma cells (*HSP90AA1*, *HSPA1A*, *HSPA1B*, *HSPA6*, *HSPB1* and *HSPD1*) from abnormal colorectal samples, especially in the ones with adenomatous polyps.

Furthermore, IgG plasma cells can be grouped into two sub-types, characteristic of high expression of immunoglobulin-encoding genes *IGKC* and *IGLC1/IGLC2*, respectively. In addition, the six clusters of IgA plasma cells can also be characterized based on the combinatory expression level of some immunoglobulin-encoding genes (*IGHA1*, *IGHA2*, *IGKC*, *IGLC1*, *IGLC2* and *IGLC3*). In summary, our analyses suggested the potential distinct functional importance of immunoglobulins and heat shock proteins in immunity and microenvironment during the colorectal malignancy.

Conclusion: Our transcriptome data provides valuable insights and a useful resource for better understanding the molecular pathological landscape in CRC to achieve more effective diagnosis and treatments.

Contact E-Mail Address: coline.desseux@uca.fr

Introduction: In patients with colorectal cancer (CRC), intestinal dysbiosis has been observed, with abnormal colonization of the colonic mucosa by pathogenic *Escherichia coli* strains producing a cyclomodulin named cytotoxic necrotizing factor (CNF). Cyclomodulins are bacterial toxins capable of altering the cell cycle of the infected cell. One of the mechanisms involved in host defence against pathogens and in carcinogenesis is autophagy. However, the role of autophagy in the host response to the infection by CNF-producing *E. coli*, designated as CyPEC, has not yet been described.

Aims & Methods: Thus, the aim of this study was to investigate the role of autophagy in colorectal carcinogenesis in the context of CyPEC infection. Mice predisposed to CRC development with autophagy deficiency specifically intestinal epithelial cells (*Apc^{Min/+}/Atg16l1^{ΔIEC}* mice) and their control littermates with functional autophagy (*Apc^{Min/+}* mice) were infected with the clinical CyPEC strain 21F8. Tumor size and number were determined using a dissecting microscope. The mouse colons were collected and used for histological score assessment, and to analyse the levels of markers of autophagy, cell proliferation, apoptosis and inflammation by immunoblot, immunohistochemical staining and ELISA.

Results: We showed that in *Apc^{Min/+}/Atg16l1^{ΔIEC}* mice, infection with the CyPEC 21F8 strain led to increases in the number and the size of colonic tumours, compared with the uninfected condition. However, this was not observed in *Apc^{Min/+}* mice. The increase in tumorigenesis in *Apc^{Min/+}/Atg16l1^{ΔIEC}* mice upon 21F8 infection versus uninfected condition was associated with increased pro-inflammatory cytokine production, enhanced cellular proliferation and decreased apoptosis in colonic epithelial cells.

Conclusion: Our results suggest that autophagy is necessary to limit the pro-carcinogenesis effects of the CyPEC 21F8 strain, thereby decreasing colorectal tumorigenesis. In another word, autophagy deficiency could be a susceptibility factor for the development of CRC in a host with colonization by CyPEC strains.

NUCLEAR TRANSLOCATION OF CNPY3 FACILITATES COLORECTAL CANCER PROGRESSION VIA ENHANCING E3 LIGASE TRIM21-MEDIATED UBIQUITINATION AND DEGRADATION OF P53 PROTEIN

X. Li¹, S. Xie¹, M. Yin¹, S. Zhu¹, S. Zhang¹

Introduction: Canopy FGF signaling regulator 3 (CNPY3) is a protein predominantly localized in the endoplasmic reticulum. Its expression is increased in several cancers, including colorectal cancer (CRC). However, how CNPY3 affects CRC progression and the function of CNPY3 translocation to the nucleus in CRC is not clear.

Aims & Methods: This study aimed to investigate the role of CNPY3 in the development of CRC. In vitro, the impacts of CNPY3 on CRC growth were evaluated by 5-Ethynyl-2'-deoxyuridine staining, colony formation, wound healing, transwell migration, and apoptosis assay. Tumor xenograft mouse models and orthotopic mouse models of colorectal cancer metastasis were used to assess in vivo. Furthermore, the underlying mechanism of CNPY3 in CRC was revealed by RT-qPCR, western blot, LC-MS/MS analysis, immunofluorescence staining, coimmunoprecipitation, GST-pulldown, confocal microscopy, ubiquitination assays, and rescue experiments.

Results: CNPY3 was significantly upregulated in CRC tissue and cell lines, correlating with their poor prognosis. Functional experiments demonstrated that CNPY3 enhances CRC proliferation, migration, invasion, and tumor growth. Notably, our investigation reveals a nucleus translocation of *cnpy3* by activation of nuclear localization sequences through protein conformational changes. Meanwhile, nuclear localization of CNPY3 promotes the binding of TRIM21 and p53 and forms a CNPY3-TRIM21-p53 complex, thereby promoting the ubiquitination-proteasomal degradation of wild-type p53 protein, inhibiting the related genes of the TP53 signaling pathway, and promoting apoptosis of tumor cells. In vivo and in vitro, inhibiting the degradation of p53 was able to suppress CNPY3 in cancer-promoting tumors, whereas the knockdown of CNPY3 in p53^{-/-} HCT116 cells did not significantly inhibit CRC.

Conclusion: CNPY3, after nuclear translocated, binds to TRIM21 and p53 and stabilizes the TRIM21-p53 interaction. This CNPY3-TRIM21-p53 complex facilitates TRIM21-mediated p53 ubiquitination and causes p53 proteasome degradation.

Collectively, these findings support that CNPY3, an oncogene with CRC progression and poor prognosis, serves as a biomarker and therapeutic target correlated to suppress p53 function.

Introduction: The incidence of early-onset colorectal cancer is increasing alarmingly worldwide, and countermeasures against this issue are urgently needed. Although previous studies suggested age-related molecular pathological changes, the association between the roles of Immunoscore using the ration of CD3+ and CD8+ T cells in anti-tumor immune responses and early-onset colorectal cancer and adenoma resected by endoscopy remains unclear.

This study aimed to investigate the association of Immunoscore using the ratio of CD3+ and CD8+ T cells and clinicopathological characteristics mainly focused on early-onset tumors. We defined early-onset colorectal tumors as those that occurred at less than 50 years of age at diagnosis and later-onset as those that occurred at 50 years of age or older in this study.

Aims & Methods: The aim of this study was to investigate the association between Immunoscore and clinicopathological features of early-onset colorectal tumors. Utilizing a molecular pathological database of 169 colorectal cancer and adenoma cases, we analyzed 306 colorectal lesions including 214 early-onset tumors resected by endoscopic procedures including cold snare polypectomy, endoscopic mucosal resection, and endoscopic submucosal dissection from February 2017 to January 2020 at Nippon Medical School Hospital in Japan.

After collecting formalin-fixed paraffin-embedded (FFPE) tissue blocks, CD3 and CD8 immunostaining was performed, and the number of CD3+ and CD8+ cells was quantified in each area of tumor, stromal, and normal. One to five fields of view (median 5 fields) were selected depending on the size of the lesion using a fluorescence microscope BZ-X800 (KEYENCE) at 200x magnification, and the average number of CD3+ and CD8+ cells was calculated by automatic counting.

Counting stromal and normal cells was limited to those specimens for which the excised specimens were large enough to contain sufficient stromal and normal portions in addition to the tumor portion. Immunoscore was calculated by the ratio of CD8+/CD3+ positive T cells. Clinicopathologic characteristics were also evaluated retrospectively. Chi-square test was used to compare categorical variables, Spearman's test to examine correlation, Mann-Whitney U test to compare continuous variables, and Kruskal-Wallis test to compare the three groups.

Results: The tumor location was 126 (41%)/142 (47%)/37 (12%) in the proximal/ distal colon/rectum. The number of CD3+T cells decreased significantly with increasing tumor diameter ($P<0.001$). The number of CD3+T cells was predominantly lower in type Ip (protruding type) compared to type non-Ip ($P<0.001$). The distribution of Immunoscore measured in tumor area was significantly different among tumor locations ($P<0.05$).

Conclusion: Using endoscopically resected specimens, we suggest that the anti-tumor immune response may differ according to tumor size, gross type, and location. Further studies are warranted to stratify early-onset tumors requiring careful surveillance after endoscopic resection in terms of the anti-tumor immune response in T cells.

Introduction: Portal vein thrombosis is a common complication of cirrhosis regardless of etiology. Medical management with anticoagulant treatment was a subject of debate with many questions about the balance between bleeding risk and therapeutic benefit. Recently, it has been proven that anticoagulant treatment improves the prognosis of liver disease and portal hypertension, without any additional bleeding risk.

Aims & Methods: The aim of our study is to identify the prognostic impact of anticoagulant treatment for portal vein thrombosis in cirrhotic patients.

It is a retrospective study including all patients followed for cirrhosis at our institution between January 2017 and August 2022. The diagnosis and monitoring of portal vein trunk recanalization were performed by Doppler ultrasound and computed tomography scan. Treatment was decided on a case-by-case basis and was dependent on the stage of liver disease, patient age, and extension of thrombus. Patients excluded: patients with portal cavernoma. upper endoscopy was systematically performed before treatment. The prognosis improvement rate was determined by the Child-Pugh score at baseline and at completion of the study.

Results: A total of 53 patients with portal vein thrombosis were included among 285 cirrhotic patients followed during this period. Portal vein thrombosis was diagnosed in 11.3% (n = 6). The mean age was 54 years, with a male-to-female ratio of 0.7 (22 males/31 females).

The etiology of cirrhosis included chronic hepatitis B in 11.3% (n = 6), chronic hepatitis C in 5.6% (n = 3), primary biliary cholangitis in 3.7% (n = 2), autoimmune hepatitis in 1.8% (n = 1), Budd-Chiari syndrome in 1.8% (n = 1), Wilson's disease in 1.8% (n = 1), and idiopathic causes in 73.5% (n = 39). Before PVT diagnosis, the Child-Pugh score was classified as follows: A in 71.6% (n = 38), B in 24.5% (n = 13), and C in 3.7% (n = 2).

The main cirrhosis decompensations were bleeding related to portal hypertension in 67.9% (n = 36), ascites in 54.7% (n = 29), and hepatocellular carcinoma (HCC) in 3.7% (n = 2).

Anticoagulant treatment was indicated in 47.1% (n = 25) of cases, 48% of patients (n = 12) were treated with low molecular weight heparin (LMWH), 44% (n = 11) with direct oral anticoagulants (DOACs), and 8% (n = 2) with acenocoumarol. Among patients treated with anticoagulants, 68% (n = 17) had hemorrhagic decompensation, 56% (n = 14) had ascitic decompensation, 8% (n = 2) had hepatic encephalopathy, and 4% (n = 1) had hepatocellular carcinoma.

	Treated Patients (n=25)	Non-Treated Patients (n= 28)	P value
Child Pugh Score Stability	40 % (n= 10)	42 % (n=12)	>0.001
Child Pugh Score Deterioration	32 % (n= 8)	35 % (n=10)	>0.001
Child Pugh Score Improvement	28% (n=7)	21,4 % (n=6)	>0.001

Table 1: Outcomes of Patients Treated with Anticoagulants vs. Untreated Patients

Conclusion: In our study, 71% of patients had a Child Pugh A score at the time of PVT diagnosis. 40% of patients maintained a stable Child score during follow-up and 28% even improved their prognostic stage.

Introduction: Recent evidence indicates that physical frailty, as assessed by liver frailty index (LFI), is an independent predictor of mortality in patients with cirrhosis. However, majority of data are from North American cohorts of patients in the outpatient clinic setting.

Aims & Methods: We prospectively investigated characteristics and impact of frailty in all patients with cirrhosis who were admitted to our unit between October 1st, 2021 and March 31st, 2023. Exclusion criteria were: age<18 or>70 years; known musculoskeletal disease; history of liver transplantation. LFI was calculated at admission and previously established thresholds were used to assess physical frailty: <3.2 (robust); between 3.2 and 4.5 (pre-frail); >4.5 (frail). Primary outcome was liver related death.

Results: One hundred-fifteen patients with cirrhosis were included (median age 60 years; 72% male), median MELD score 22 (IQR 14-26). 68.5 % of patients were CHILD C class. Presence of ascites were the most frequent sign of significant clinical portal hypertension (79.3% of patients). Alcohol was the most common aetiology of cirrhosis (62%). At time of inclusion, 42% of patients were frail (median LFI 4.23; IQR 3.62-4.72). During hospitalization patients with CHILD C class and frailty were admitted to the ICU for further decompensation of liver disease more frequently than patients with CHILD A/B class (11% vs. 0% p=0.034) and without frailty (19.1% vs. 6.3%, p=0.037). When discharged, patients with frailty were more frequently re-hospitalized when compared with patients without frailty (78.8% vs. 55.8%, p=0.028). No differences in rate of re-hospitalization were observed according to Child class (p=0.474). Fifty-eight patients (50% Child C) died during follow up of which 66.7% were frail and 33.3 % not frail (p=0.003), median time of follow up were 279 days (IQR 59-513). At univariate analysis Meld score>22, presence of ascites and presence of frailty were found to be associated with shorter survival, however at multivariate analysis, MELD score (OR:2.74; 95% CI 1.478-5.059 p=0.001) and frailty (OR:3.45; 95% CI 1.83-6.52, p=0.000) were the only independent predictor of death.

Conclusion: Frailty is frequent among hospitalized patients with cirrhosis, with a higher rate of ICU admission during hospitalization and re-hospitalization after discharge. The presence of frailty resulted strongly associated with an increased risk of death; This study opens the need of larger and multicentric studies looking

at physical frailty in the context of hospitalized patients with cirrhosis. Understanding the contribution of frailty to outcomes can ultimately optimize the management of patients during hospital stay especially in those who may benefit from early interventions including physical rehabilitation and nutritional supports.

Introduction: Percutaneous liver biopsy (PC-LB) is the gold standard for the study of chronic liver disease. However, it is limited to patients with appropriate clinical and hematological conditions. Transjugular liver biopsy (TJ-LB) represents a less invasive yet less available technique. Endoscopic ultrasound-guided liver biopsy (EUS-LB) has emerged as a minimally invasive readily available technique. To the best of our knowledge, no network meta-analysis has compared LB quality and related adverse events among these techniques.

Aims & Methods: A systematic search was run in PubMed, Embase, Web of Science and Cochrane. The search included studies from inception to November 2023, in adult patients, which compared at least two of the following techniques: EUS-LB, PC-LB or TJ-LB. The analyzed endpoints were mean total sample length (TSL), mean number of complete portal triads (CPT), rate of appropriate sample for diagnosis, sample fragmentation and major adverse events (hematomas, bleeding, perforation, death). There was no distinction regarding study design, biopsy needle type or assistance with additional imaging methods. The studies with insufficient data, without any reported endpoint, or case series were excluded. The PC-LB was the reference. Data was analyzed in Rv4.0.

Results: Over the last thirty years (1993 to 2023), 21 original studies were analyzed being: 18/21 full manuscripts; 15/21 retrospective, 3/21 prospective, 3/21 randomized clinical trials (RCT); 11/21 EUS-LB, 21/21 PC-LB and

16/21 TJ-LB; 5/21 EUS-LB vs PC-LB, 10/21 PC-LB vs TJ-LB, and 6/21 compared the three techniques. We scrutinized 620 EUS-LB patients, 3347 PC-LB, and 1901 TJ-LB. TSL pooled mean for EUS-LB, PC-LB, and TJ-LB was 28.6 ± 10.6 mm, 23.3 ± 13.5 mm, and 15.7 ± 9.0 mm, respectively. Pooled rate of appropriate sample for diagnosis was 96.6%, 89.2%, and 85.4%, with a major adverse events pooled rate of 4%, 2.9%, and 3.5%, respectively. Between 14 studies and 24 pairwise comparisons, TSL EUS-LB mean was 0.17 mm longer (p=.932), but TJ-LB 4.93 mm shorter (p=.0025) (I²=95%). Between 3 studies and 5 pairwise comparisons, relative risk (RR) of sample fragmentation was significantly higher for EUS-LB (RR 4.55; 95% CI 2.72 – 7.61; p<.001) and TJ-LB (RR 2.72; 95% CI 1.54 - 4.80; p<.001) (I²=0%). There was not significant difference among mean number of CPT (I²=97.3%), rate of appropriate sample for diagnosis (I²=48.7%) or major adverse events (I²=10.5%).

Conclusion: EUS-LB quality is comparable to PC-LB and superior to TJ-LB in terms of TSL. These techniques are comparable in terms of the mean number of CPT, rate of appropriate sample for diagnosis, and major adverse events. Further original studies are needed to define the sample fragmentation rate of the aforementioned.

Introduction: Infection is the main cause of decompensation in liver cirrhosis (LC) and contributes to high mortality. Infection by multidrug-resistant microorganisms (MDRO) is becoming increasingly prevalent, and there is evidence that it reduces survival in LC.

Aims & Methods: A 6-year retrospective analysis was carried out on a cohort of patients with LC admitted due to infection between October 2017 and March 2018. MDRO was defined as resistance to at least 3 antibiotic classes. The survival time in weeks from the date of MDRO isolation or date of hospitalization to the date of death was evaluated. SPSS was used to reproduce Kaplan-Meier (KM) survival curves.

Results: 31 patients were included, 17 of whom had MDRO isolation vs. 14 without MDRO isolation (N-MDRO) during the 2017-2018 period. After the analysis period, 30 patients had died. A lower survival rate was observed in patients with MDRO isolation, with a mean survival rate of 37.9 weeks vs. 61.5 weeks for N-MDRO, although without statistical significance (p=0.7). From the subgroup analyses carried out, there was also a statistically non-significant lower average survival in the MDRO group: analyzing patients without a diagnosis of hepatocellular carcinoma (23 patients),

there was an average survival of 47.9 weeks in the MDRO (12 patients) vs 75.7 weeks in the N-MDRO group ($p=0.74$); and in the subgroup with Child Pugh <C (12 patients), there was an average survival of 29.6 weeks in the MDRO (9 patients) vs 110.6 weeks in the N-MDRO group ($p=0.18$).

Conclusion: The results of this cohort, although not statistically significant, suggest that MDRO infection has an impact on the decreased survival of patients with LC, particularly in patients who would expect a longer survival.

References: Kaplan Meier curves of survival will be presented.

Introduction: A systemic inflammatory response syndrome (SIRS) is linked to red cell distribution width (RCDW), which produces pro-inflammatory signals that act directly on hematopoietic stem cells in the bone marrow. This stimulation may cause alterations in the membrane of red blood cells (RBCs), as assessed by RCDW, which have been linked to increased morbidity and death in a number of systemic disorders.

Aims & Methods: This study aims to evaluate RCDW as a predictor of outcome in hospitalized cirrhotic patients.

This prospective cross-sectional study was conducted on 1000 patients. The outcome was assessed by days of hospitalization; mortality in hospitalized patients or during short-term follow-up (3 months) and rehospitalization during follow-up of 6 months.

Table 1. Relation between outcome of patient and its relation to child score

Results: Male represented 69.6%. Mean age was 57.67 ± 13.07 years old. Baseline co-morbidities were recorded as the presence of diabetes mellitus (200 patients) and hypertension (400 patients). Hepatitis C virus was the commonest etiology of the diseased liver (90%). Child-Pugh classes A, B and C of studied patients represented (21.2%, 38.8% and 40%). The survived patients during follow-up represented 63.3%. Area under the curve for RCDW was 0.923 (95% CI, 0.904–0.943), 0.910 for C-reactive protein (95% CI, 0.890–0.930), 0.904 for Hb (95% CI, 0.883–0.925) and 0.903 for platelets (95% CI, 0.882–0.924). RCDW cutoff point at 21.35 for predicting survival had sensitivity 93%, specificity 91%, accuracy 92%, positive predictive value 85 and negative predictive value 96. Regression analysis revealed a significant positive association between both RCDW and white blood cells with mortality.

Table 1 shows that there was a significant difference among the groups (child A.B.C) regarding outcome which represented by MELD score days of hospitalization and number of hospitalization during follow up as MELD score was highest in child C patient (40.8) compared with child B patient (24.6) and group A (21.8) and also hospitalization days was highest in child C (17.8) compared with child B (10.23) and group A (2.55)

Conclusion: RCDW could provide useful information for predicting the length of hospitalization and survival in hospitalized cirrhotic patients.

Introduction: According to Baveno VII, non-invasive-based criteria is useful to rule in or out for clinically significant portal hypertension (CSPH) in advanced chronic liver disease (ACLD). Liver stiffness measurement (LSM) and platelet count (PLT) are the two parameters considered in this field, particularly LSM ≥ 25 kPa is highly predictive for CSPH, while LSM ≤ 15 kPa plus PLT ≥ 150 G/L exclude CSPH. Spleen Stiffness Measurement (SSM) can be used in ACLD patients, identifying patients with a low probability (SSM <40 kPa) of having high-risk varices.

Aims & Methods: The aim of our study is to explore the utility of SSM in predicting endoscopic signs of portal hypertension and its added value compared to LSM and platelet count. This retrospective study was conducted at the University of Naples “Federico II”. All patients with ACLD (for any etiologies) with at least LSM ≥ 10 who underwent esophagogastroduo-

denoscopy (EGD) for portal hypertension assessment within one year before Spleen Stiffness measurement were enrolled. Exclusion criteria were patients < 18 yrs, PLT>150*10³/cc, liver transplantation, HCC patients, portal vein thrombosis and incomplete data. The study population was divided in three groups: the first includes patients with LSM≥25, the second patients with LSM≥15 and <25 and the third patients with LSM≥10 and <15. **Results:** Sixty-nine patients (41 male, mean age 62.7±14.8 years old) were recruited. The main etiology was virus-related (30 patients, 43.4%) followed by metabolic (13 patients, 18.8%), alcohol (12 patients, 17.4%), autoimmune (7 patients, 10.1%) and other (7 patients, 10.1%). Fifty-five patients were Child A and 14 patients were Child B. Overall, mean LSM was 24.7±12.9 kPa, mean SSM was 59.8±23.5 kPa and mean PLT count was 102±50*10³/cc. The groups were composed by 25, 27 and 17 patients, respectively. Eighteen out of 25 patients (69.2%) belonging to the first group had endoscopic sign of PH and almost all of them (17/18, 94.4%) had SSM≥40kPa. In the second group a lower rate of endoscopic sign of PH was found (14/27, 51.8%), although SSM had a high diagnostic performance (100%). Finally, in the third group, in which according to Baveno VII the pre-test probability of CSPH is low, 5 out of 17 (29.4%) had endoscopic sign of PH and, among them, 60% of patients (3/5) had SSM>40kPa. Indeed, SSM demonstrated a better positive correlation with the presence of endoscopic sign of PH (Pearson coefficient r=0.4) than LSM (r=0.3). **Conclusion:** SSM enhances the diagnostic performance of LSM and PLT assessment proposed by Baveno VII in predicting portal hypertension in patients with ACLD.

Introduction: Gastroesophageal varices are present in approximately 50% of cirrhotic patients¹. The cirrhosis-related age-standardized mortality is high². Gastroesophageal variceal bleeding is a medical emergency with a mortality rate of approximately 10-20% at six weeks¹, and rebleeding incidence ranged from 32% to 84%³, and even higher, around 90%, in patients receiving no antiviral therapy⁴. Endoscopic variceal ligation (EVL) and endoscopic variceal obliteration (EVO) with cyanoacrylate are recommended for patients with acute variceal bleeding⁵, but both treatments have no impact on portal pressure⁶. Portal hypertension is the primary pathophysiological mechanism underlying gastroesophageal varices. Non-selective beta-blockers (NSBBs) induce vasodilation by targeting beta-receptors on blood vessels and the heart, reduce cardiac output through negative inotropic effects, thereby reducing portal blood flow and associated portal pressure^{7,8}. Gastroesophageal varices type 1 (GOV1) and type 2 (GOV2) are varices in direct continuity from the esophagus to the stomach (lesser and greater curvatures, respectively)⁹. We chose EVL after EVO for treatment of GOV1 and GOV2, which tended to have a better secondary prophylactic effect according to our clinical experience. How-

ever, no prior research has evaluated the effect of additional NSBB under these circumstances. It remains unclear whether the addition of NSBB provides further benefit after *combined* use of tissue adhesive and endoscopic variceal ligation for bleeding gastroesophageal varices.

Aims & Methods: We retrospectively analyzed cirrhotic patients (mainly due to hepatitis B and C) who received endoscopic combined treatment of gastroesophageal varices and were assigned or not to NSBB treatment as a second prophylaxis. Subanalysis was done for ascites, portal vein thrombosis, splenectomy, and Child-Pugh grade. 5-year overall survival and rebleeding rates were compared between treatment groups.

Results: A total of 490 patients were analyzed, and 130 patients received additional NSBB treatment. Although the additional NSBB treatment did not lead to a statistically significant difference in overall 5-year survival (Log-rank test, p = 0.133), it did reduce the 5-year rebleeding rate from 45.7% to 30.64% (Log-rank test, p = 0.002, univariate COX analysis, HR 0.57, 95% CI 0.39-0.82), consistent with the comparison after propensity score matching. Neither overall survival nor bleeding differed significantly between propranolol and carvedilol. NSBB (HR 0.54, 95% CI 0.37-0.79, p = 0.001) and splenectomy (HR 0.65, 95% CI 0.44-0.96, p = 0.030) were independent factors in reducing rebleeding, rather than improving survival, in cirrhotic patients who received combined endoscopic treatment. In patients without splenectomy, NSBB treatment improved overall survival (Log-rank test, p = 0.019, univariate COX analysis, HR 0.43, 95% CI 0.21-0.89) and reduced rebleeding rates (Log-rank test, p = 0.001, univariate COX analysis, HR 0.52, 95% CI 0.34-0.78).

Conclusion: We show for the first time that adding NSBB to *combined* endoscopic therapy significantly reduced recurrent variceal bleeding (GOV1 & GOV2) in cirrhotic patients, yet did not improve overall survival, except for patients without splenectomy. The addition of NSBB for patients receiving *combined* endoscopic treatment of gastroesophageal varices provides benefits but does not prolong overall survival.

THE RESPONSE OF GUT MICROBIOTA TO ARSENIC METABOLISM IS INVOLVED IN ARSENIC-INDUCED LIVER INJURY, WHICH IS INFLUENCED BY THE INTERACTION BETWEEN ARSENIC AND METHIONINE SYNTHASE

Z. Weng¹

¹Nanjing Medical University, School of Public Health, China

Contact E-Mail Address: wengzhenkun@njmu.edu.cn

Introduction: Arsenic, a potent environmental toxin, has been widely reported to cause significant health problems, including liver damage and disturbances in the metabolic processes. One of the lesser-understood facets of arsenic toxicity is its impact on gut microbiota, the community of microorganisms living in the intestinal tract, which plays a crucial role in host metabolism and overall health. Previous studies have indicated that arsenic exposure can alter the composition of gut microbiota, potentially affecting the host's metabolism of arsenic and exacerbating its toxic effects. Despite ongoing research, the mechanisms underlying the interaction between arsenic exposure, gut microbiota changes, and arsenic metabolism remain inadequately defined.

Aims & Methods: The primary objective of this study was to elucidate the dynamics of gut microbiota changes under varying levels of arsenic exposure and to understand how these changes affect arsenic metabolism and subsequent liver toxicity. We used C57BL/6 mice as a model system, exposing them to 0, 5, or 10 ppm sodium arsenite (NaAsO₂) in their drinking water over a period of six months. We conducted a comprehensive analysis of the gut microbiota, focusing on folic acid (FA)/vitamin B12 (VB12)- and butyrate-synthesizing communities. Additionally, molecular interactions between arsenic and methionine synthase (MTR), an enzyme crucial for FA/VB12 utilization, were assessed using 3D molecular simulations and biochemical assays. The intervention model involved supplementation of FA and VB12 to evaluate their protective effects against arsenic-induced disturbances.

Results: Exposure to NaAsO₂ significantly altered gut microbiota, with a notable increase in the abundance of FA/VB12- and butyrate-synthesizing microbiota. This shift was hypothesized to compensate for the disrupted utilization of these nutrients due to arsenic exposure. In higher arsenic exposure levels, however, the microbiota changes were inconsistent, suggesting a potential threshold beyond which the compensatory mechanism may be overwhelmed. Biochemical assays confirmed that arsenic binds to MTR, disrupting its function and further impacting FA/VB12 metabolism. The interaction was substantiated by SEC-UV-DAD and fluorescence-labeled arsenic studies, which demonstrated that arsenic directly interacts with MTR in both non-cellular and cellular systems. Our intervention model using FA and VB12 supplementation showed that it was possible to mitigate the disturbances in gut microbiota, restore MTR levels, enhance arsenic metabolism, and reduce liver injury.

Conclusion: This study provides significant insights into the interaction between arsenic exposure and gut microbiota. We demonstrated that changes in gut microbiota are not merely a consequence of arsenic exposure but are intricately linked to the metabolic processes affected by arsenic, particularly through the disruption of MTR function. The supplementation of FA and VB12 proved effective in blocking these disturbances, suggesting potential therapeutic strategies to combat arsenic toxicity. The findings emphasize the importance of considering gut microbiota in the management and treatment of arseniasis and underscore the complex interplay between environmental toxins, gut microbiota, and host metabolism. Future studies should focus on further delineating the specific pathways and mechanisms by which microbiota influence arsenic metabolism and exploring the potential for microbiota-targeted therapies in arsenic-related diseases.

Introduction: Spontaneous bacterial peritonitis (SBP) is a severe complication of liver cirrhosis, carrying life-threatening consequences. Pathophysiologically, SBP emerges from bacterial translocation from the gut to the peritoneal cavity. The mechanisms of bacterial interaction with intestinal epithelial cells remain incompletely understood. We showed that patients with liver cirrhosis exhibit a thinner intestinal mucus layer, facilitating direct interaction between bacteria and epithelial cells. This interaction results in the degradation of cell junctions, tissue damage, and cellular stress (Haderer et al., Gut 2022). p53 and its family members p63 and p73 are important regulators of cellular stress responses. This study investigates the relationship between expression of p53 family members and paraptosis, a bacterial-induced form of programmed necroptotic cell death.

Aims & Methods: HCT-116 cells with different p53/p73 status (p53KO, p73KO, p53/p73 double KO) were co-cultured *Escherichia coli* (*E. coli*) O6:Hnt and harvested in 30-minute intervals for up to 4 hours. We investigated cell death mechanisms using specific inhibitors (zVAD, actinomycin D). Cell death rates were determined by flow cytometry using Annexin V / DAPI staining. Protein expression of p53 and p73 was evaluated by Western Blot. Changes in cell morphology were examined via electron microscopy.

Results: Bacterial co-culture induced paraptosis in intestinal epithelial cells, characterized by distinct morphological alterations such as mitochondrial swelling, dilatation of the endoplasmic reticulum, cytoplasmic vacuolization, and chromatin condensation at the nuclear membrane. Bacterial-triggered cell death was accompanied by a paraptosis-specific protein profile. Actinomycin D effectively inhibited paraptosis in HCT-116 cells irrespective of their p53/p73 status. Notably, upon bacterial contact, protein levels of p53 and p73 were initially upregulated, followed by gradual degradation. CRISPR/Cas9-mediated knockout of p53 family members resulted in modified kinetics of cell death progression, with the absence of either p53 or p73 delaying paraptosis induction.

Conclusion: Bacterial co-culture induces paraptosis in intestinal epithelial cells, with the p53 family influencing the kinetics of cell death. A comprehensive molecular characterization of this process is of crucial clinical relevance, as the p53 status in the intestinal epithelium influences paraptosis susceptibility. Induction or stabilization of p53 and p73 could thus be a therapeutic option for the prevention and treatment of SBP.

Introduction: Direct-acting antivirals (DAA) have revolutionized the treatment landscape for chronic hepatitis C (CHC), yielding notably high sustained virological response (SVR) rates. While SVR is associated with reduced hepatocellular carcinoma (HCC) risk, recent studies emphasize the importance of ongoing surveillance, particularly in patients with advanced fibrosis (F3-F4), mainly within the initial three years post-SVR.

Aims & Methods: The aim of this study was to assess the risk of hepatocellular carcinoma over a five-year period following DAA-induced SVR in a real-life cohort of F3-F4 patients.

Data were retrospectively collected from CHC F3-F4 patients initiating DAA treatment between February 2015 and January 2017 at a tertiary center. Statistical analysis was performed with SPSS 29.0 (significance level ≤ 0.05).

Results: Out of 239 patients included (69.5% male; median age: 58 years), a SVR at 12 weeks rate of 96.6% was achieved. Among those with SVR and continued follow-up (n=229), 5.2% (n=12) developed HCC over the five-year period, with 50% occurring more than three years post-SVR.

The annual HCC incidence rate was 1.1 cases/100 person-years (33.3% HCC-related mortality rate). Most HCC cases occurred in males (75%) and cirrhotic patients (75%, Child-Pugh A: 77.8%). The mean alpha-fetoprotein level at HCC diagnosis was 156.1 ng/mL. Additionally, 75% of patients who developed HCC had other co-factors for liver disease, mainly metabolic. Comparing the presence of other liver disease co-factors, no statistically significant difference was found between those who developed HCC and those who did not during the five-year follow-up period (p-value 0.267).

Conclusion: The incidence rate of HCC post-SVR has been reported to be 0.9-2.96/100 person-years for DAA therapy, consistent with the findings of this investigation. Nevertheless, our study underscores that the risk of HCC persists for at least five years following SVR, warranting long-term surveillance. Contrary to previous research, there is insufficient evidence to support the involvement of other co-factors in HCC development.

Introduction: Blood elevation of pancreatic enzymes is generally associated with clinical symptoms and represent biological sign of pancreatic pathology. Occasionally, serum elevation of pancreatic enzymes can be found in asymptomatic patients while performing routine laboratory tests and be related to a condition termed Chronic Asymptomatic Pancreatic Hyperenzymemia (CAPH).

Aims & Methods: The purpose of this study was to evaluate the diagnostic management of asymptomatic chronic pancreatic hyperenzymemia and to assess the true prevalence of CAPH in a tertiary care center. Patients who referred to the specialist outpatient pancreatic clinic at the University Hospital Policlinico Umberto I in Rome for asymptomatic pancreatic hyperenzymemia, from September 2021 to September 2023, were enrolled. Inclusion criteria were: age over 18 years, 2 years of follow-up with availability of at least 2 magnetic resonance cholangiopancreatography, and serial determination of serum pancreatic enzymes in the absence of known pancreatic pathology. Subjects with positive history of pancreatic pathology, known causes of hyperenzymemia and history of alcohol intake greater than 40 g/day (males) and 20 g/day (females) were excluded. At the end of two years, the diagnosis of CAPH was made in asymptomatic subjects with persistent pancreatic enzyme elevation who had no relevant pancreatic changes on imaging.

Results: 41 patients were included in the study [median age 68 (31-84) years, 15 Males and 26 Females]. In 22/41 (54%) patients, organic pancreatic alterations were found on the 2nd level imaging examination, 54.5% (12/22) of them requiring specific follow-up: 9/22 (41%) patients had intraductal papillary mucinous neoplasms (IPMNs) and 3 (14%) chronic pancreatitis. Additional findings were 4 (29%) ectasia of the pancreatic ductal system, 3 (14%) sphincter and ampullary abnormalities, 2 (9%) cases of pancreas divisum and 1 (4%) cystadenoma. In the remaining 19/41 (46%) patients, monitored for 24-months follow-up, no pancreatic organic changes were found and a diagnosis of CAPH was made. No differences in risk factors for pancreatic diseases were found between patients with organic alterations and patients with CAPH: smoking 27 vs 26%, alcohol consumption below the exclusion limits 13 vs 21%, BMI 24.5 vs 23, respectively. A positive family history for pancreatic diseases was found in 50% of the subjects for each group, without any specific familiarity for asymptomatic chronic pancreatic hyperenzymemia.

Conclusion: A comprehensive diagnostic work-up is essential in cases of occasional asymptomatic findings of elevated pancreatic enzymes; more than half of the patients underlying organic pancreatic disease that requires specific periodic follow-up. After 2 years of follow-up, the diagnosis of CAPH was made in the other half of patients.

Introduction: Triglyceride glucose (TyG) index is a new biomarker for metabolic disorders. The relationship between diabetes mellitus (DM), obesity, non-alcoholic fatty liver disease and TyG index has been determined in recent studies, but there is no study on pancreatic steatosis, which is a relatively new entity. This study aimed to determine the relationship between TyG index and pancreatic steatosis.

Aims & Methods: This study was conducted based on the data of patients included in the 'Turkey Pancreatic Steatosis Prevalence Study' conducted by the TGD Pancreas Study Group. Demographic data and clinical information of the patients were collected. TyG index was calculated with the formula 'ln [fasting triglycerides (mg/dL) × fasting plasma glucose (mg/dL)/2]'. Pancreatic steatosis was evaluated with abdominal ultrasonography (USG) by experts in this area.

Results: 1700 patients were included in the study. There were 967 women (56.9%) and 733 men (43.1%). Mean ages, respectively; 48.6±24, and 47.25±15 years. Body mass indexes (BMI) were 27.3±5.6 and 27.05±4.04.

347 (26.4%) of the participants were diagnosed with metabolic syndrome (MS), 230 (17.2%) were diagnosed with DM, and 319 (23.9%) were diagnosed with hypertension. Hepatosteatois was detected in 943 (55.5%) and pancreatosteatois was detected in 1132 (69.9%) in USG. Mean TyG index was 4.69±0.32. A statistically significant, positive ($r=0.334$, $r=0.383$, $r=0.206$, $r=0.299$, respectively) correlation was detected between the TyG index and BMI, waist-hip circumference and HOMA-IR ($p<0.05$). Mean TyG index; It was significantly higher in individuals with HT, DM, MS and pancreatic steatosis ($p<0.05$).

Conclusion: TyG index is a relatively new biomarker that indicates the metabolic profile. This is the first study conducted between pancreatic steatosis, which awareness has just increased and TyG index. TyG index was found to be statistically significantly higher in individuals with pancreatic steatosis.

Disclosure: Nothing to disclose.

THE COMBINATION OF YKL-40 AND INTERLEUKIN 6 PREDICTS MORE ACCURATELY THE SEVERITY OF ACUTE PANCREATITIS THAN EITHER BIOMARKER ALONE: A CROATIAN SINGLE-CENTER PROSPECTIVE OBSERVATIONAL STUDY.

Introduction: Acute pancreatitis (AP) often has unpredictable and complicated clinical course. Numerous biochemical predictors may aid in the risk stratification of AP (including interleukin 6 (IL-6)), but none of them are accurate. YKL-40 is glycoprotein playing mayor role in inflammation and angiogenesis, with reported average serum concentrations of ≥ 190 ng/mL in inflammatory diseases. It has been shown that IL-6 stimulates the production of YKL-40 and, in reverse, YKL-40 (at least in some tissues) induces the production of IL-6.

Aims & Methods: The aim of our study is to assess whether combined concentrations of both YKL-40 and IL-6 could be more informative in risk stratification of developing more severe form of AP than concentrations of either biomarker alone.

We included 150 consecutive consenting adults with AP admitted to Sestre milosrdnice UHC, Zagreb (June 2020-June 2023). Patients with any acute/chronic diseases known to be associated with dysregulated expression of YKL-40 were excluded. Alongside routine laboratory studies (including C-reactive protein (CRP)), 7 mLs of blood were withdrawn for determining YKL-40 and IL-6 concentrations on admission and 48h after. Severity of disease was defined using revised Atlanta classification. Blood samples for YKL-40 and IL-6 quantification in 30 consenting non-AP adults consistent with previously mentioned exclusion criteria were withdrawn. They were matched 1:1 by age and sex to randomly selected 10 patients from each of AP severity categories. Analysis were performed using enzyme-linked immunosorbent assays. AP patients were classified into 2 categories for each biomarker (based on YKL-40 and IL-6 concentrations on admission and 48h after): 1. for YKL-40: low (<190 ng/mL) and high (≥ 190 ng/mL); 2. for IL-6: low (<42 pg/mL) and high (≥ 42 pg/mL). Cumulative multimodal logit models were fitted to ordinal outcome "AP severity" – using raw data,

and data after entropy balancing undertaken to balance the two categories of YKL-40 and IL-6 concentrations on age, sex, time between symptom onset and admission, and CRP concentrations.

Results: The results showed lower YKL-40 (<50 ng/mL) and IL-6 (<20 pg/mL) concentrations in 30 non-AP adults compared to AP patients. At both time points (on admission and 48h after), odds of more severe AP were clearly higher with YKL-40 and IL-6 concentrations above vs. below the cut-off values (190 ng/mL and 42 pg/mL, respectively), and were particularly higher in patients with both cytokines above the cut-off vs. patients with both cytokines below the cut-off. The same relationship was maintained with adjustments for age, body mass index, days elapsed since symptom onset and admission, and for CRP concentrations – however, the strength of association was lower. This is in line with the fact that high CRP concentration predicts more strongly severe AP forms when taken 48h after compared to admission.

This phenomenon was apparent also when the interaction term was included in the model: at CRP concentrations 45 mg/L, neither YKL-40, or IL-6 or their combination above the cut-off values were associated with the outcome; at CRP concentrations 90 mg/L, odds were higher, and were particularly high for a combination of high YKL-40 and high IL-6. The same was observed at CRP concentrations 180 mg/L.

Conclusion: Overall, data suggest that combined YKL-40 and IL-6 concentrations in acute AP, taken either on admission or 48h after, predict more strongly moderate and/or severe (vs. mild) AP than either cytokine alone, and do so 'on-top' of the CRP concentrations.

Introduction:

In patients with acute pancreatitis (AP), prolonged hospitalization and pro-inflammatory processes create conditions conducive to deep vein thrombosis (DVT) formation. Despite this, there is a scarcity of research on the incidence and risk factors specific to DVT development in hospitalized AP patients.

Aims & Methods: We conducted a retrospective analysis of 402 medical data from patients who were hospitalized with AP at our gastroenterology department of a university hospital from January 2018 to December 2023. The study included patients who underwent abdominal and pelvic

computed tomography (CT) and our objective was to determine the prevalence of DVT in hospitalized AP patients and evaluate its influence on morbidity and mortality.

Results: Among 402 patients with acute pancreatitis (AP), 5.5% (n=22) developed DVT, with Portal vein thrombosis in 54.5%, Splenic vein thrombosis in 32%, and Superior mesenteric vein thrombosis in 13.6%. The mean age among patients with DVT was 58 ± 22 years compared to 56 ± 18 years (P=0.03). DVT incidence was significantly higher among patients with a Computed Tomography Severity Index score of ≥ 3 (63.6%, P=0.02). Among patients with pleural effusion, 13.7% without thrombosis and 31.8% with thrombosis were observed (P=0.02). An association was found between Systemic Inflammatory Response Syndrome (SIRS) and thrombosis, with 16.1% of patients with persistent SIRS not developing thrombosis compared to 40.9% with thrombosis (P=0.006). Similarly, among patients with a Bedside Index for Severity score > 2, 15.0% without thrombosis and 31.8% with thrombosis were observed (P=0.03). Among patients with WON, 6.9% without thrombosis and 35.0% with thrombosis were observed (P<0.001). The mean CRP level was significantly higher in patients with thrombosis (187 ± 100 vs 130 ± 107 mg/dL, P=0.02). Hypoalbuminemia was significantly more frequent in cases of thrombosis (P=0.002). During follow-up, among patients with pancreatic insufficiency, 0.9% without thrombosis and 10.0% with thrombosis were observed (P=0.001). However, no significant association was observed between thrombosis and mortality rate.

Conclusion: In summary, our study reveals the prevalence of DVT in AP patients, emphasizing its clinical significance. Factors such as higher severity scores and association with systemic inflammation underscore the importance of proactive management to mitigate DVT risk and enhance patient outcomes.

CLINICAL AND BIOCHEMICAL OUTCOMES OF AGGRESSIVE FLUID RESUSCITATION VERSUS CONSERVATIVE FLUID RESUSCITATION IN PATIENTS WITH ACUTE PANCREATITIS

I.O. Vargas Olmos¹, M.C. Peláez Luna²

¹The American British Cowdray Medical Center, Internal Medicine - Gastroenterology, Mexico City, Mexico, ²The American British Cowdray Medical Center, Gastroenterology, Mexico City, Mexico

Introduction: Acute pancreatitis is one of the most frequent and critical gastrointestinal diseases, therefore adequate management is essential to impact the prognosis of patients. Despite advances in the understanding of the pathophysiology of the disease and its complications, management remains a challenge and is mainly based on fluid resuscitation, pain management and early enteral nutrition.

Fluid resuscitation is the cornerstone of initial management, and acute pancreatitis treatment guidelines recommend early and aggressive hydration, however, evidence regarding what type of solution as well as what velocity of infusion should be used, is limited. There is not an established dose of intravenous fluids to prevent or reverse progression to multiple organ failure and reduce overload complications.

Aims & Methods: The main objective is to compare the clinical and biochemical outcomes of patients with acute pancreatitis who receive aggressive fluid resuscitation versus those who receive conservative fluid resuscitation after the first 48 hours of treatment.

195 patients were included, which were divided into two groups: 30 patients who received aggressive fluid resuscitation (more than 2.5 ml/kg/h) and 165 patients who received conservative fluid resuscitation (less than

2.5 ml/kg/h) during the first 48 hours of hospitalization. A second division of groups was performed based on 48-hour fluid balance: 129 patients who had a global fluid balance more than (>) positive 4000 ml and 66 patients who had a global fluid balance less than (<) positive 4000 ml.

Results: Patients with aggressive fluid resuscitation had a statistically significant smaller increase in C-reactive protein delta compared to conservative fluid resuscitation (+ 5.2 vs + 6.8, p 0.035) at 48 hours of treatment. Patients who had a 48-hour fluid balance > 4000 ml had a significantly greater increase in C-reactive protein delta (+ 11.46 vs + 3.94, p 0.012) compared to < 4000 ml 48-hour fluid balance, as well as longer time to start oral intake (79.36 vs 55 hrs, p 0.024) and greater requirement for loop diuretics (33.3% vs 14.8%, p 0.006).

Outcome	Global balance	Mean	p	Fluid resuscitation	Mean	p
C-reactive protein delta at 48 hours (mg/dl)	< 4000 ml	+3.94	0.012	< 2.5 ml/kg/h	+6.86	0.035
	> 4000 ml	+11.46		> 2.5 ml/kg/h	+5.2	
Creatinine delta at 48 hours (mg/dl)	< 4000 ml	-0.27	0.86	< 2.5 ml/kg/h	-0.14	0.73
	> 4000 ml	+0.26		> 2.5 ml/kg/h	+0.25	
BUN delta at 48 hours (mg/dl)	< 4000 ml	-3.53	0.177	< 2.5 ml/kg/h	-1.47	0.66
	> 4000 ml	+3.62		> 2.5 ml/kg/h	+2.11	
Leukocyte delta at 48 hours (10 ⁹ /L)	< 4000 ml	-1.87	0.171	< 2.5 ml/kg/h	-1.68	0.30
	> 4000 ml	-1.14		> 2.5 ml/kg/h	-1.3	
In-hospital days	< 4000 ml	5.81	0.237	< 2.5 ml/kg/h	5.83	0.30
	> 4000 ml	6.48		> 2.5 ml/kg/h	6.87	
Analgesia requirement (h)	< 4000 ml	67.62	0.147	< 2.5 ml/kg/h	73.39	0.64
	> 4000 ml	97.63		> 2.5 ml/kg/h	105.44	
Oral intake time (h)	< 4000 ml	47.5	0.024	< 2.5 ml/kg/h	55.48	0.28
	> 4000 ml	79.8		> 2.5 ml/kg/h	79.36	
Requirement for loop diuretics (%)	< 4000 ml	14.8	0.006	< 2.5 ml/kg/h	12	0.67
	> 4000 ml	33.3		> 2.5 ml/kg/h	19	

A multivariate analysis was performed and we found a significantly greater decrease in hematocrit percentage at 48 hours in patients with aggressive fluid resuscitation compared to the conservative resuscitation group, which was concordant with greater hemodilution and higher doses of intravenous fluids.

Conclusion: Aggressive fluid resuscitation is associated with lower changes in levels of C-reactive protein delta compared to conservative fluid resuscitation, as long as patients do not have a 48-hour fluid balance greater than 4000 ml at 48 hours, because at this point the levels of delta C-reactive protein and delay in starting oral intake are greater compared to patients with a global balance less than 4000 ml, in addition to requiring loop diuretics in a higher percentage.

Contact E-Mail Address: sushmii88official@gmail.com

Introduction: Changes in body composition of patient with acute pancreatitis (AP) may stem from various causes such as anorexia secondary to proinflammatory state, abdominal pain, vomiting, ileus, sepsis etc and they can have a considerable effect on the disease outcome.

Aims & Methods: This study aimed to evaluate changes in body composition and development of sarcopenia in patients with moderately severe acute pancreatitis (MSAP) and severe acute pancreatitis (SAP) over short term follow up. This was a Single-centre observational study conducted in a tertiary care centre in northern India. Body composition analysis was done using bioelectrical impedance (BIA) method and sarcopenia assessment was done with hand grip strength (HGS) using digital hand dynamometer and skeletal muscle index (SMI) at 3rd lumbar vertebral (L3) level using computed tomography (CT) at baseline (admission) and after 8 weeks.

Results: A total of 40 patients were included (MSAP-22 and SAP-18). Mean age was 39.4 ± 14.6 years and 75% (30) were males. The predominant etiologies were alcohol (47.5%) and gallstone disease (37.5%). The mean BISAP score was higher in SAP than MSAP (2.17 ± 0.71 vs 1.05 ± 0.79, P < 0.001) and most common organ failure in SAP was acute lung injury (88.9%). In both MSAP and SAP there was significant change in body mass index (BMI), body fat percentage, subcutaneous fat percentage, whole body muscle percentage and visceral fat level between baseline and after 8 weeks. There was significant reduction in SMI at 8 weeks in both MSAP and SAP (47.5 ± 10.5 vs 41.5 ± 7.3, p < 0.001 and 48.9 ± 10.2 vs 41.2 ± 8.5 p < 0.001 respectively) but no significant difference in HGS was observed in both MSAP and SAP over 8 weeks follow up. On comparison between MSAP and SAP patients, the decline in BMI tend to be more pronounced in SAP, however the difference did not reach significant level (Table 1). Using European consensus definition, prevalence of probable sarcopenia and sarcopenia in MSAP and SAP at follow up were (68% and 22.7%) and (66% and 22.1%) respectively.

Introduction: Chronic pancreatitis (CrP) is a fibroinflammatory disease that progresses with the loss of both exocrine and endocrine parenchyma of the pancreas due to fibrosis resulting from chronic inflammation (1). Chronic abdominal pain is the most common clinical feature in CrP, which is a malnutrition syndrome (2). Alcohol is the most common cause of CrP (3).

Sarcopenia is defined as a decrease in total body muscle mass (4). Sarcopenia is associated with adverse outcomes in CrP patients.(5).The prevalence of sarcopenia is increased in CrP patients compared to the normal population(6). In a study by Olesen et al., the frequency of sarcopenia in CrP patients was found to be 17%, and they found that sarcopenia was associated with a decrease in the general health. In this study, PEI, smoking and narcotic analgesic use were defined as risk factors for sarcopenia (7). Pancreatic exocrine insufficiency (PEI) is one of the most common complications of chronic pancreatitis. In a study by Kempeneers et al., mild and severe PEI in CrP patients were reported %31 and %46, respectively (8). The prevalence of osteopathy is high in patients with CrP and may increase the risk of fractures. In a meta-analysis of 19 studies by Amanda Koh et al., it was shown that 19% of the patients diagnosed with chronic pancreatitis were osteoporotic and 37% were osteopenic (9).

Aims & Methods: The prevalence of sarcopenia, pancreatic exocrine insufficiency (PEI) and osteopathy is high in chronic pancreatitis (CrP), and these are important complications with adverse consequences. The aim of our research is to evaluate the prevalence and risk factors of sarcopenia, PEI and osteopathy in CrP patients.

83 CrP patients were included in the study.

The surface area of the paravertebral muscles was measured from the third lumbar region of the cross-sectional images; PVMl was used to assess sarcopenia. PFE was used to evaluate PEI, and results were reported as no PEI, mild, or severe. DEXA was used to evaluate osteopathy. EORTC PAN26 and a semiotic questionnaire were performed. CBC, routine biochemical tests and vitamin/mineral levels were measured at the same time of PFE.

Results: The prevalence of sarcopenia, PEI, and osteoporosis was found to be 19 (22.9%), 56 (67.5%), and 18 (21.7%), respectively.

Male gender (OR:4.9 and p=0.044), severe PEI (OR:4.2 and p=0.043), smoking (OR:4.6 and p=0.040) and zinc deficiency (OR:2.2 and p=0.029) were defined as risk factors for sarcopenia.

Of the 83 patients, 20 were diagnosed with mild and 36 with severe PEI, and PEI was not detected in 27 patients. Severe PEI was determined to be associated with osteoporosis/osteopenia (p=0.010), DM (p=0.001), heavy narcotic analgesic use (p=0.030), sarcopenia (p=0.016) and zinc deficiency (p=0.012).

Osteoporosis was detected in 18 patients and 42 patients had osteopenia. PAN26 scores were higher in individuals with osteoporosis (p=0.029). Female gender (OR:7.8 and p=0.004), severe PEI (OR:8.1 and p=0.003) and sarcopenia (OR:5 and p=0.037) were identified as independent risk factors for osteopathy.

Conclusion: The prevalence of sarcopenia, PEI and osteopathy are increased in CrP. Smoking, zinc deficiency, PEI, and male gender are defined as risk factors for sarcopenia. The prevalence of osteopathy increases in patients with sarcopenia and is associated with decreased quality of life. PVMl was used for the first time to evaluate sarcopenia in CrP patients.

In studies evaluating sarcopenia using cross-sectional imaging methods, zinc deficiency was identified as a risk factor for sarcopenia for the first time in the literature.

EFFICACY AND SAFETY OF ERCP IN PATIENTS WITH SYMPTOMATIC PANCREAS DIVISUM

R. Ben Haj Ali¹, M. Yakoubi¹, A. Ben Mohamed¹, G. Gharbi¹, M. Mahmoudi¹, A. Khsiba¹, M. Medhioub¹, M.L. Hamzaoui¹

Introduction: Pancreas divisum is the most frequent congenital anomaly of the pancreas. It arises from failed fusion of the dorsal and ventral pancreatic ducts. In symptomatic patients, the endoscopic intervention is proposed as first-line treatment via retrograde cholangiopancreatography (ERCP). In case of failure, surgery remains a feasible option.

Aims & Methods: The aim of this research was to evaluate the efficacy and safety of ERCP in the treatment of patients with symptomatic pancreas divisum.

We conducted a retrospective and descriptive study including ERCP procedures performed between January 2014 and February 2024. We collected clinical and radiological data regarding patients in whom the diagnosis of symptomatic pancreas divisum was confirmed. The success of ERCP was defined by the ability to perform minor papilla sphincterotomy with or without dorsal duct stent insertion. The adverse events of ERCP as well as the long term outcome of each patient were collected during follow up.

Results: During the study period, 22 procedures were carried out in patients with this anomaly. The median age was 44.5 years (14 years - 72 years) with a male-to-female ratio of 0.83. The diagnosis was made during the exploration of recurrent acute pancreatitis in 10 patients, a first episode of acute pancreatitis in 8 patients, recurrent abdominal pains in 3 patients and chronic pancreatitis in one patient. The most observed variant of the anomaly was complete pancreas divisum in 15 patients. The incomplete variant was observed in 3 patients. The variant with isolated dorsal duct was found in 2 patients and 1 case of pancreas divisum associating an ansa pancreatica was identified. Endoscopic treatment was successful in 15 patients with a success rate of 77.3%. The main therapeutic option was sphincterotomy of the minor papilla alone in 13 patients and, in addition, placement of a stent in the dorsal pancreatic duct in the other 2 patients. Intervention failure was mainly associated with the inability to catheterize the minor papilla in 5 patients. Failure to visualize the minor papilla and stenosis of the duodenal bulb were the other causes of failure.

No subsequent complications post-ERCP were reported. During follow up, no endoscopic reintervention due to symptoms reoccurrence was necessary.

Conclusion: In our study, endoscopic treatment of pancreas divisum in symptomatic patients was successful in 77.3% of the cases. Sphincterotomy alone or with stent placement were the preferred therapeutic options, allowing symptom relief in all patients. Although these techniques carry numerous risks, no complications occurred during the subsequent patient follow-up.

Disclosure: Nothing to disclose.

Introduction: It is unknown how stent types relate to clinical outcomes of endoscopic ultrasound (EUS)-guided drainage of pancreatic pseudocysts. This multicenter retrospective study aimed to compare the clinical outcomes between a lumen-apposing metal stent (LAMS) and a plastic stent.

Aims & Methods: Among 357 patients with pancreatic fluid collections in a large multi-institutional WONDERFUL consortium, we included 123 patients who received EUS-guided drainage of a pancreatic pseudocyst (16 and 107 cases with LAMS and plastic stent(s), respectively). We examined clinical treatment success, procedure-related adverse events, and pseudocyst recurrence.

Results: There were no differences between the groups regarding demographics (e.g., age and sex) and disease characteristics (e.g., size, encapsulation status, and the timing of drainage in relation to the onset of acute

pancreatitis). The clinical success rates were comparable between the LAMS and plastic stent groups (94% vs. 87%, respectively; $P = 0.40$). The stent types were not associated with the time to clinical success (median, 25 days vs. 22 days for the LAMS and plastic stent groups, respectively; $P = 0.56$), the overall rate of procedure-related adverse events (0% vs. 5.6%, $P = 0.33$), or the rate of recurrence following clinical success (6.7% vs. 17%, $P = 0.19$).

Conclusion: In patients receiving EUS-guided drainage of pancreatic pseudocysts, clinical outcomes appeared to be comparable between the LAMS and plastic stent groups. If validated, our findings would support the feasibility of plastic stents in this patient population, which is a more cost-effective treatment modality than LAMSs. We, the WONDERFUL study group, have launched a randomized non-inferiority trial of plastic stents compared to a LAMS in this setting (NCT#06133023).

Introduction: Chronic pancreatitis represents a risk for pancreatic cancer with an estimated effect of 16 in the first 2 years, 7.9 in the first 5 years and over 3 in 9 years. The sensitivity of endoscopic ultrasound fine needle aspiration (EUS-FNA) in diagnosing pancreatic malignancy in cases with and without chronic pancreatitis drops from 91.5% to 65.3%. Although contrast-enhanced fine needle aspiration (CH-EUS-FNA) was not statistically superior to standard EUS-FNA in diagnosing solid pancreatic lesions, some emphasis was placed on the usefulness of CH-EUS-FNA in cases of pancreatic masses on chronic pancreatitis.

Aims & Methods: Aim. To assess and compare the diagnostic rate of CH-EUS tissue acquisition (CH-EUS-TA) compared to standard EUS-TA in cases of solid pancreatic masses with features of chronic pancreatitis.

Material and methods. This is a retrospective unicenter study from 2020 to 2022 that included solid pancreatic masses (solid component > 80%) that required EUS-guided sampling and features of chronic pancreatitis that needed EUS tissue acquisition. We excluded patients with previous

surgery or chemotherapy for pancreatic diseases, contraindications for tissue sampling or without 1-year follow-up in negative cases. We divided patients in two groups: group 1 with CH-EUS-FNA and group 2 with standard FNA, both using 22G needles. The final diagnosis was based on FNA or surgery results or on 1-year follow-up.

Results: There were 13 patients included in group 1 and 27 patients included in group 2. The sensitivity for malignancy was 85% in group 1 and 80% in group 2. No difference was proved regarding size or mass location, percentage of definitive chronic pancreatitis between groups. The most common lesion location was the head of the pancreas (60%), while the mean mass size was 2,4 cm. Less than 50% of patients (42%) were classified as "Definitive Chronic Pancreatitis" according to Rosemont Criteria. Regarding the severity of disease according to Cambridge Severity Score, the largest group (45% of patients) was the "Cambridge 3" group. 45% of the patients required main bile duct stenting for main bile duct stenosis. A small percent of patients (15%) showed signs of portal hypertension. In group 1, the hypo-enhancement was observed in 38.4% of patients.

Conclusion: In this retrospective series, the CH-EUS-FNA proved to perform similarly with EUS-FNA when chronic pancreatitis features were noticed. Further studies using EUS fine needle biopsy (EUS-FNB) contrast guided procedures are needed in this category of patients.

Introduction: *Helicobacter pylori* (*Hp*) infection is one of the major causes of gastric cancer and represents a significant global public health challenge. In Japan, where the incidence of gastric cancer is high, reducing the risk through the eradication of *Hp* is deemed crucial. While enhancing awareness about *Hp* is thought to encourage testing and contribute to treatment, there is a lack of evaluation regarding the Japanese population's awareness of *Hp*.

Aims & Methods: In this cross-sectional study, we aim to assess baseline knowledge and attitude towards *Hp* among Japanese population. Participants were recruited through an online survey platform (Macromill, Inc), with ages ranging from 20 to 69, reflecting the age demographic composition of Japan equally across genders. Referencing the existing surveys on *Hp*¹⁻³, we assessed knowledge on five key aspects related to *Hp*: risk of infection (scored out of 7), diseases caused by *Hp* (scored out of 7), methods of testing (scored out of 5), benefits and side effects of *Hp* eradication (scored out of 8), and knowledge of gastric cancer prevention (scored out of 10). Attributes of participants, socioeconomic factors, and health literacy (HLS-14)⁴ were also evaluated to study their correlation with knowledge about *Hp*.

Results: A total of 3,095 individuals participated. Of these, 56.3% reported having some knowledge about *Hp*. 865 participants (28.0%) had undergone *Hp* testing, 354 (11.4%) confirmed *Hp* infection, and 283 (9.1%) had received treatment for *Hp*. About 55.6% (1,722 participants) consider that the treatment for *Hp* posed a significant financial burden. The average correct response rate across all knowledge items was 45.6% (SD: 19.0%). The individual correct response rates were 57.3% for risk of *Hp* infection, 50.9% for diseases caused by *Hp*, 24.5% for methods of testing, 45.6% for benefits and side effects of *Hp* eradication, and 44.4% for knowledge of gastric cancer prevention. Higher scores were significantly associated with having an income over 4 million yen, a family history of *Hp*, personal *Hp* testing history, *Hp* treatment history, and higher health literacy. Over 80% of respondents acknowledged that understanding the relationship between *Hp* and stomach symptoms, recognizing *Hp* as a gastric cancer risk, and knowing that *Hp* eradication reduces future gastric cancer risk influenced their decision on the need for eradication. Similarly, the same proportion reported that believing that the harshness of the treatment exceeds the current symptoms and the high costs of testing and treatment influenced their decisions for eradication.

Conclusion: The level of understanding of *Hp* among the Japanese population is moderate and influenced by income level, health literacy, and personal experience with the *Hp* infection. Many consider testing and treatment burdensome. Enhancing correct understanding of *Hp* could potentially increase testing and treatment rates, contributing to the future reduction of gastric cancer in Japan.

Introduction: The development of gastric cancer is strongly linked to *Helicobacter pylori* infection. Therefore, early diagnosis and eradication of *H. pylori* infection can significantly lower the risk, as studies consistently show reduced cancer rate with these measures. The success in achieving such a goal depends on widespread early detection and treatment, plus effective prevention of new infections. To date, there is no effective certified vaccine against *H. pylori* available. This study describes the development of a novel multi-epitope *H. pylori* vaccine consisting of B- and T-cell epitopes from six conserved virulence factors of the bacteria.

Aims & Methods: Through comprehensive bioinformatic analysis, sixteen B- and T-cell epitopes were carefully selected, considering both MHC classes I and II for the T-cell epitopes. The recombinant Multi-Epitope-Unit antigen (MEU) was combined with flagellin as adjuvant. Additionally, recombinant Modified Vaccinia virus Ankara (MVA) encoding the MEU antigen was generated. The vaccine candidates were tested in mice. To this end, two sets of animal experiments were designed. One set to evaluate the immunogenicity of the new MEU construct, while the second set to assess the protective effect of the vaccine candidates. In the vaccination protocol, both protein- and MVA-based vaccine candidates were administered intramuscularly (IM) to C57/BL6 mice on days 0, 7 and 14. Two weeks after the last immunization, mice in the prevention groups were challenged with three doses of the mouse adapted *H. pylori* SS1 strain. The groups, allocated for evaluating the immunogenicity of the new vaccine, were not exposed to infection with *H. pylori* or any further treatments prior to the analysis. Humoral (antibody) and cellular immune responses, along with the levels of protection and infection, were evaluated at two or four weeks post-immunization or -infection respectively. Bacterial load in prevention groups was determined through culturing of the gastric samples. The reactivity of anti-MEU antibodies, raised in immunized animals, to the *H. pylori* clinical isolates was also assessed via ELISA employing crude antigens of a set of 30 clinical isolates.

Results: The MEU antigen, whether adjuvanted with flagellin or in MVA construct, was observed to elicit significant antibody levels in mice, capable of reacting with crude antigens from *H. pylori*. The most substantial antibody response was detected towards the individual epitopes from Urease and Flid (hook-associated protein 2 homologue).

Both vaccine protocols, using the flagellin-adjuvanted MEU and the recombinant MVA, demonstrated complete protection against *H. pylori* infection compared to non-immunized animals. This protection was achieved through either a schedule of immunization with the protein-based vaccine candidate followed by MVA boost or two administered doses of MVA.

Conclusion: The novel MEU-based vaccine demonstrated significant immunoreactivity against *H. pylori* antigens. Our findings indicate a complete protection against *H. pylori* infection in the mice immunized with the multi-epitope unit antigen, regardless of the vaccination protocols. The reactivity of these antibodies with the bacteria native crude antigens suggests the antigen's correct processing by the mammalian immune system. Moving forward, our next step involves assessing the therapeutics effects of the vaccine candidate.

Disclosure: Nothing to disclose.

Introduction: The role of indications for *Helicobacter pylori* investigation on prescriptions and effectiveness is uncertain.

Aims & Methods: To assess the appropriateness of indications for *H. pylori* treatment, and its influence on prescriptions and effectiveness. International, prospective, non-interventional registry of the management of *H. pylori* infection by European gastroenterologists (Hp-EuReg). Treatment-naïve patients registered from 2013 to July 2023 at e-CRF AEG-REDCap were included. Effectiveness was evaluated by modified intention-to-treat analysis.

Results: Overall, 53,636 treatment-naïve patients from 34 countries were analyzed. Indications were inappropriate in 2,989 (5.6%) cases. Most common indications were: dyspepsia with normal endoscopy (49%), non-investigated dyspepsia (20%), duodenal ulcer (11%), gastric ulcer (7.7%), and gastroesophageal reflux disease (GERD) (2.6%). Treatment effectiveness varied by indication: duodenal ulcer (91%), gastric ulcer (90%), preneoplastic lesions (90%), dyspepsia with normal endoscopy (89%), GERD (88%), and non-investigated dyspepsia (87%); $p<0.001$. Bismuth quadruple therapies reached 90% effectiveness in all indications except GERD. The effectiveness with PPI-bismuth-metronidazole-tetracycline (quadruple-BMTc) was lower in patients treated for non-investigated dyspepsia as compared to those with dyspepsia with normal endoscopy, however, in all cases cure rates were optimal (91.8% vs. 93.9%, $p=0.047$). In Spain, these latter results were also confirmed in the same indications (92% vs. 94%, $p<0.05$), and similar scenario was observed for quadruple-BMTc in patients with dyspepsia from Russia and Italy, but did not reach statistical significance. PPI-clarithromycin-amoxicillin-bismuth showed similar effectiveness rates for dyspepsia with normal endoscopy and non-investigated dyspepsia (93%), also confirmed in Spain, Russia and Azerbaijan. Concomitant clarithromycin-amoxicillin-tinidazole/metronidazole (CAT-CAM) achieved 90% except in patients with non-investigated dyspepsia. Most of concomitant-CAT-CAM therapies (36%) were prescribed in Spain, where the effectiveness was suboptimal in patients with non-investigated dyspepsia (87%), dyspepsia with normal endoscopy (89.8%) and GERD (89%) ($p<0.001$). Triple therapies showed suboptimal eradication rates in all indications with the exception of Lithuania, where optimal effectiveness was observed in patients with non-investigated dyspepsia (99%, $p=0.009$). Adverse events were higher in patients treated for dyspepsia with normal endoscopy as compared to duodenal ulcer (23% vs. 28%, $p<0.001$). Therapeutic compliance was higher in patients with duodenal ulcer and preneoplastic lesions (98% and 99%, $p<0.001$).

Indications, n (%)	Spain	Russia	Azerbaijan	Italy	Slovenia	Lithuania	Others	Total
Triple-CA								
Non-investigated Dyspepsia	577 (75.3)†	348 (84.9)	37 (92.5)	31 (68.9)†	378 (89.6)	68 (96.6)*	920 (82.1)†	2,359 (82.1)†

Table 1. Overall effectiveness (by modified intention-to-treat) of first-line treatment schemes.

A: Amoxicillin, B: Bismuth salts, C: Clarithromycin, GERD: gastroesophageal reflux disease, M: Metronidazole, Tc: Tetracycline. Group “Success” (*) or “Failure” (†) statistically significant.

Conclusion: In Europe, indications for *H. pylori* investigation could be improved in 5.6% of patients. Higher effectiveness was observed in patients treated for gastric or duodenal ulcers and preneoplastic lesions. Bismuth and non-bismuth quadruple therapies reached optimal results in almost all indications.

Introduction: The V Spanish Consensus Conference on *H. pylori* recommends as first-line treatment either a non-bismuth quadruple concomitant regimen (PPI, clarithromycin, amoxicillin, and metronidazole) for 14 days or a bismuth-containing quadruple therapy (PPI, bismuth, tetracycline, and metronidazole in a single-capsule) for 10 days. The superiority of one treatment over the other is currently not established.

Aims & Methods: To compare the effectiveness and safety of first-line empirical concomitant treatment versus bismuth quadruple therapy as single-capsule in Spain.

All treatment-naïve patients registered in AEG-REDCap in the Spanish cohort of the European *H. pylori* Registry (Hp-EuReg) from 2013 to 2023, treated with either concomitant therapy or the single-capsule, were evaluated. First, a set of pre-selected variables evaluated variations in prescriptions, observing significant differences in following: year of visit, geographical region, and patient age. Therefore, a propensity score analysis (SMR) was conducted and included in the multivariate logistic regression model to determine the modified intention-to-treat effectiveness (mITT) of both treatments. Additionally, a multivariate analysis with 10,000 bootstrap replicas was performed, balancing for geographical region and including associated variables.

Results: A total of 11,720 treatments were analysed: 6,293 (54%) with concomitant therapy (for 10 and 14 days) and 5,427 (46%) consisting of single-capsule (10 days). Concomitant therapy, both for 10 and 14 days, was associated with lower mITT effectiveness (88%; OR=0.53; [95% CI 0.43-0.66]; and 90%; OR=0.62; [0.53-0.73], respectively) compared to single-capsule therapy (93% mITT, $P<0.001$). Compliance (OR=6.81; [5.05-9.15]), presence of ulcer (OR=1.49; [1.17-1.91]), and central geographical region (OR=2.51 [1.94-3.29]) were the variables associated with greater eradication success ($P<0.001$). However, there was no demonstrated benefit of using high-dose (equivalent to 80 mg omeprazole twice daily) PPI compared to standard dose (equivalent to 40 mg omeprazole twice daily). Compliance was higher with single-capsule (98%) compared to 10- and 14-days concomitant therapy (both 97%). The incidence of adverse effects was lower with concomitant therapy for 10 days (25%) than for 14 days (33%); and the latter was significantly higher than with single-capsule (25%) ($P<0.0001$). Regarding serious adverse effects, 9 (0.1%) and 7 (0.1%) cases were reported with concomitant therapy and single-capsule therapy, respectively.

Conclusion: In Spain, bismuth-containing quadruple therapy prescribed as single-capsule is more effective and better tolerated than non-bismuth quadruple concomitant treatment.

Introduction: In Latin America, the *Helicobacter pylori* infection is a common problem (prevalence of 47-63%)^{1,2}. There is limited information regarding the best approach for *Helicobacter pylori* infection management in Latin America.

Aims & Methods: Our aim was to describe the most frequent eradication therapies, their effectiveness, adherence, and safety.

A multicenter, prospective, international registry (Hp-LATAMReg; Hp-WorldReg partner) was conducted. Information about therapies used by gastroenterologists in seven countries (Argentina, Chile, Colombia, Costa Rica, Ecuador, Mexico, and Peru) from 2015 to 2024 was registered at e-CRF AEG-REDCap platform. The modified intention-to-treat (mITT) effectiveness, safety, and adherence were analysed for the first-line regimens. The length of the treatment and the proton pump inhibitor (PPI) dose prescribed were also evaluated.

Results: Overall, 2,511 patients were registered, of which 2,323 (93%) were treatment-naïve. The most commonly prescribed first-line therapies (n=2,216, 88%) were: standard clarithromycin-based triple therapy (PPI-amoxicillin-clarithromycin; n=801, 30%), PPI-clarithromycin-amoxicillin-metronidazole (n=369, 14%), dual therapy (PPI-amoxicillin; n=274, 10%), PPI-metronidazole-doxycycline-bismuth (n=201, 7.6%), PPI-metronidazole-tetracycline-bismuth (n=186, 7.1%), PPI-amoxicillin-metronidazole-bismuth (n=156, 5.9%), PPI-clarithromycin-amoxicillin-bismuth (n=119, 4.5%), and PPI-amoxicillin-levofloxacin (n=110, 4.2%). Most of those regimens (n=2,055, 93%) were optimized, that is prescribed for 14 days and almost 50% of the patients were administered high-dose PPIs (54 to 128 mg omeprazole equivalents b.i.d.) (n=967, 46%) with significant differences between schemes (p<0.01) (Table 1).

	Prescription (% , n)							
	PPI-C-A (27%, n=801)	PPI-C-A-M (15%, n=366)	PPI-A (11%, n=274)	PPI-M-Tc-B (7.3%, n=185)	PPI-C-A-B (4.2%, n=118)	PPI-A-M-B (6.7%, n=156)	PPI-A-L (3.7%, n=109)	PPI-M-D-B (7.9%, n=201)
mITT eradication rate (% , n) (p<0.01*)	75%, n=595	89%, n=327	88%, n=241	87%, n=160	79%, n=93	95%, n=148	74%, n=81	87%, n=172
Side effects rate (% , n) (p<0.01*)	35%, n=281	41%, n=151	7.3%, n=20	12%, n=23	18%, n=21	47%, n=72	20%, n=22	48%, n=97
Adherence rate (% , n) (p<0.01*)	98%, n=779	99%, n=363	98%, n=269	97%, n=181	98%, n=117	97%, n=152	99%, n=109	96%, n=193
High-dose PPIs use (% , n) (p<0.01*)	25%, n=192	31%, n=105	98%, n=267	73%, n=132	22%, n=25	65%, n=100	43%, n=44	52%, n=102
High-dose PPIs mITT cure rate (% , n) (p<0.01*)	69%, n=131	85%, n=88	88%, n=236	93%, n=123	72%, n=18	97%, n=97	77%, n=34	83%, n=85
14 days use (% , n) (p<0.01*)	89%, n=697	98%, n=358	99%, n=273	99%, n=184	95%, n=105	100%, n=156	90%, n=99	97%, n=195
14-days and high-dose PPIs use (% , n) (p<0.01*)	23%, n=185	26%, n=96	99%, n=266	71%, n=131	21%, n=25	64%, n=100	37%, n=40	49%, n=98
14-days and high-dose PPIs mITT cure rates (% , n) (p<0.01*)	74%, n=115	90%, n=84	89%, n=236	93%, n=122	72%, n=18	97%, n=97	80%, n=32	85%, n=83

Table 1. Effectiveness by modified intention-to-treat, safety, and compliance of first-line empirical therapy.

*Chi square test. mITT = modified intention to treat; PPI = Proton pump inhibitor; C = clarithromycin; A = amoxicillin; B = bismuth salts; M = metronidazole; L = levofloxacin; Tc = tetracycline; D = doxycycline; high-dose PPIs (54 to 128 mg omeprazole equivalents b.i.d.).

The first-line mITT overall effectiveness ranged from 74% to 95%, being the PPI-amoxicillin-metronidazole-bismuth the only therapy achieving optimal (90%) cure rates. However, when therapies were optimised (i.e.; 14 days and high-dose PPIs) the following also provided optimal (>90%) effectiveness: PPI-clarithromycin-amoxicillin-metronidazole (90%); PPI-metronidazole-tetracycline-bismuth (93%) and PPI-amoxicillin-met-

ronidazole-bismuth (97%). The dual therapy PPI-amoxicillin provided encouraging mITT results (89%) and had the lowest incidence rate of side effects (7.3%); whereas the highest was reported with PPI-metronidazole-doxycycline-bismuth (48%). Good adherence, defined as >90% of drug intake, was observed in 98% (n=2,163) of cases (Table 1).

Conclusion: In Latin America, bismuth quadruple therapy with PPI-amoxicillin-metronidazole-bismuth and optimized (14-day and high-dose PPIs) quadruple therapies either with PPI-clarithromycin-amoxicillin-metronidazole and PPI-metronidazole-tetracycline-bismuth provided optimal (>90%) effectiveness. Dual therapy with PPI-amoxicillin provided encouraging results (close to 90% cure rates) and had the lowest incidence rate of adverse events.

Introduction: In Latin America, the *Helicobacter pylori* infection is a common problem (prevalence of 47-63%)^{1,2}. There is limited information regarding the best approach for *Helicobacter pylori* infection management in Latin America.

Aims & Methods: Our aim was to describe the *H. pylori* diagnostic tests and treatments' indications in Latin America.

A multicenter, prospective, international registry (Hp-LATAMReg; Hp-WorldReg partner) was conducted. Data were collected by gastroenterologists in seven countries (Argentina, Chile, Colombia, Costa Rica, Ecuador, Mexico, and Peru) from 2015 to 2024 and registered at e-CRF AEG-REDCap platform. The most frequent indications for treatment and diagnostic tests before and after eradication treatment were evaluated.

Results: Overall, 2,497 patients were registered, of which 1,680 (67%) were female. The mean (SD) age of the patients was 53 (14) years, with 1,087 patients (44%) from Mexico, 446 (18%) from Peru, 343 patients (14%) from Chile, 274 (11%) from Argentina, 200 (8%) from Colombia, 104 (4.2%) from Costa Rica, and 43 (1.7%) from Ecuador. Among those, 2,186 (88%) were treatment-naïve cases. The most frequent indications for treatment were non-investigated dyspepsia (n=995, 40%) and dyspepsia with normal endoscopy (n=690, 28%) (Table 1). The main *H. pylori* diagnostic methods before the eradication treatment were histology (n=1,642, 66%), rapid urease test (n=354, 14%) and ¹³C-urea breath test (UBT) (n=298, 12%). One diagnostic test was used in 2,471 (99%) cases, and 1,985 (80%) patients were diagnosed with invasive tests. To assess post-treatment eradication, the most frequent *H. pylori* diagnostics tests used were stool antigen monoclonal test (n=1,016, 41%), ¹³C-UBT (n=635, 25%) and ¹⁴C-UBT (n=516, 21%). There were statistical differences between the countries regarding the indication for treatment and the diagnostic methods before and after the eradication therapy.

Country	Argentina (n=274)	Chile (n=343)	Colombia (n=200)	Costa Rica (n=104)	Ecuador (n=43)	Mexico (n=1,087)	Peru (n=446)	Overall (n=2,497)
Indication of <i>Helicobacter pylori</i> eradication	p<0.001*							
Non- investigated dyspepsia	27 (9.9%)	45 (4.5%)	36 (18%)	2 (1.9%)	0 (0%)	700 (65%)	185 (42%)	995 (40%)
Dyspepsia with normal endoscopy	201 (74%)	202 (58%)	16 (8%)	15 (14%)	1 (2.3%)	33 (3%)	176 (39%)	644 (26%)
Duodenal Ulcer	13 (4.8%)	8 (2.3%)	5 (2.5%)	8 (7.7%)	1 (2.3%)	45 (4.1%)	9 (2%)	89 (3.6%)
Gastric Ulcer	13 (4.8%)	7 (5.1%)	13 (6.5%)	8 (7.7%)	7 (16%)	75 (6.9%)	14 (3.1%)	137 (5.5%)
Preneoplastic lesions	0 (0%)	2 (0.6%)	0 (0%)	19 (18%)	31 (67%)	67 (6.1%)	33 (7.4%)	152 (6.1%)
First-degree relatives of patients with gastric cancer	2 (0.7%)	12 (3.5%)	9 (4.5%)	10 (9.6%)	2 (4.7%)	19 (1.8%)	16 (3.6%)	70 (2.8%)
Screening to prevent gastric cancer	0 (0%)	0 (0%)	0 (0%)	1 (1%)	1 (2.3%)	17 (1.6%)	10 (2.2%)	29 (1.2%)
Other	6 (2.2%)	64 (19%)	109 (54%)	41 (39%)	0 (0%)	121 (11%)	2 (0.4%)	343 (14%)

Conclusion: This is an update³ of the first multicenter international registry on *H. pylori* management in Latin America (Hp-LATAMReg). There was marked heterogeneity between the countries regarding the main treat-

ment indications and the most frequently used diagnostic tests for *H. pylori* infection. The inclusion of more countries is necessary to improve the representativeness of the region.

H. PYLORI: BISMUTH QUADRUPLE THERAPY WITH DOXYCYCLINE IS AN EFFECTIVE THERAPY IN AN IRISH COHORT

Introduction: There has been a reduction in the rate of successful eradication for *H. pylori* in recent years, which has been largely attributed to increasing antibiotic resistance to traditional therapies. In areas of high clarithromycin & metronidazole resistance such as ours, Bismuth Quadruple Therapy (BQT) is a recommended first line therapy. In Ireland BQT has only recently been adopted, with doxycycline rather than tetracycline being employed for reimbursement reasons.

Aims & Methods: We aimed to assess efficacy of BQT therapy for *H. pylori* eradication in an Irish cohort.

All patients testing positive for *H. pylori* via OGD or UBT in a 2 Irish tertiary centres were treated prospectively with BQT (Bismuth 120mg QDS, Metronidazole 400mg TDS, Doxycycline 100mg BD & Esomeprazole 40mg BD x 14 days) over a period of 8 months. Eradication was confirmed with UBT at least 4 weeks after cessation of therapy (A delta-over-baseline >4% was considered positive) or by stool antigen testing, as available. Patient demographics and treatment outcomes were recorded, analysed and controlled for basic demographics and prior *H. pylori* treatment

Results: To date 122 BQT-treated patients with post-eradication testing were identified, 60(49%) female, mean age 50 years, 99 (80%) patients were treatment-naïve. Overall, 108 (89%) had successful *H. pylori* eradication. There was no association between successful eradication and age or gender (p= 0.1546 and 0.0336 respectively).

BQT first line treatment success was significantly higher than for subsequent treatments (92/99) 93% versus (16/23) 70% OR 5.7, 95%CI 1.7 – 18.6, p <0.00 3. Neither age nor gender were significant predictors of outcome (p=0.0594)

Conclusion: BQT as first line therapy for *H. pylori* infection is highly effective in a high dual resistance population. Doxycycline substitution for tetracycline still achieved > 90% eradication. BQT as second line treatment as expected performed less well, and should no longer despite the complicated regime be reserved for rescue therapy.

Contact E-Mail Address: mybaldeo@stlukes.com.ph

Introduction: H. pylori infection has affected approximately 50% of the world's population with the rates being higher in developing countries than in developed ones. Conventional proton-pump inhibitors (PPIs) have been used as first-line treatment for this condition. However, potassium competitive acid blockers (PCABs) were recently developed which may offer beneficial effects than PPIs.

Aims & Methods: This meta-analysis aims to assess the effectiveness of Potassium competitive acid-blocker against Proton pump inhibitors for the eradication of H. pylori among adults with H. pylori infection.

Electronic search of randomized controlled trials comparing H pylori eradication rate of P-CAB and PPI-based therapy was done. Quality assessment used the Modified Cochrane risk-of-bias tool, and statistical analysis was performed using ReviewManager 5.4.1

Results: Fifteen RCTs with 4129 participants who received H pylori eradication therapy comparing potassium competitive acid blockers (Tegoprazan, Vonoprazan, and YH808) with proton pump inhibitors were analyzed. H. pylori eradication rate of potassium competitive acid blocker-based therapy was higher than that of PPI-based triple therapy RR 1.04, CI 1.10-1.18, P < 0.05.

Subgroup analysis showed that PCABs based regimens had significantly higher eradication rates than PPI in treatment naive patients (RR 1.14, 95% CI 1.1-1.18, pP < 0.05) and that Vonoprazan based regimen in particular had superior eradication rates compared to PPI based regimens (RR 1.16 95% CI 1.12-1.20 P < 0.05).

No significant differences were seen between the Tegoprazan and YH4808 groups compared to the PPI group. Adverse events were also lower in the PCAB group compared to the PPI group.

Conclusion: A significant challenge that is being faced by current PPIs include nocturnal acid reflux despite treatment with twice daily PPI, and additional dosage of H2-receptor blocker at bedtime which deters successful control of gastritis under PPI treatment.

Our study shows that potassium competitive acid blockers are effective and have significantly higher eradication rates compared to PPI, with lower incidence of adverse events.

Introduction: *Helicobacter pylori* treatment's effectiveness decreases as treatment eradication attempts fail.
Aims & Methods: To evaluate the use and effectiveness of empirical rescue therapies on third and subsequent lines, in Europe.
Sub-study of the the European Registry on *H. pylori* Management (Hp-Eu-Reg), an international, multicenter, prospective, non-interventionist registry starting in 2013 aiming to evaluate the decisions and outcomes of *H. pylori* management by European gastroenterologists (38 countries, 400 researchers). All infected adult patients were systematically registered at AEG-REDCap e-CRF until December 2023, all cases with three or more

eradication attempts were extracted. Only the empirically prescribed therapies were considered. Effectiveness was analysed by modified intention-to-treat (mITT) and per protocol (PP). Data were subject to quality review.
Results: In total, 3,351 rescue treatments were included: 2,349, 688, 228 and 86 in third-, fourth-, fifth- and sixth-line treatments, respectively. Mean age was 51 years, 68% of patients were women and 5.3% were allergic to penicillin. Sixty-eight different treatment schemes were used, being the three-in-one single-capsule bismuth quadruple therapy the most commonly prescribed (Table). Overall effectiveness was 73% by mITT, and 74% by PP analyses. Bismuth quadruple therapy as single-capsule provided the highest mITT overall cure rate (84%) and achieved 87% when optimised with high-dose PPIs ($p>0.05$). Quadruple PPI-bismuth-tetracycline-metronidazole achieved optimal eradication rate (91% by mITT), only when high-dose PPIs and 14-day prescriptions were used. The use of doxycycline instead of tetracycline was associated with lower eradication rates in classical bismuth quadruple therapies ($p<0.05$).

Rescue therapy	Use, N (%)	n	Modified intention-to-treat	n	Per-protocol
			Effectiveness, % (95% CI)		Effectiveness, % (95% CI)
PPI-Single capsule B-Tc-M	796 (25%)	741	84 (81-87)	718	85 (83-88)
Triple PPI-A-L	486 (15%)	380	80 (76-84)	374	81 (77-85)
Triple PPI-A-R	363 (11%)	317	70 (65-75)	309	71 (66-76)
Quadruple PPI-A-L-B	275 (8.7%)	246	74 (69-80)	239	75 (70-81)
Quadruple PPI-B-Tc-M	243 (7.7%)	230	68 (62-74)*	222	69 (63-75)
Quadruple PPI-C-A-M	147 (4.7%)	137	65 (57-73)	134	66 (57-74)
Quadruple PPI-B-D-M	120 (3.8%)	116	63 (54-72)	112	63 (54-73)
Triple PPI-C-A	75 (2.4%)	66	59 (46-72)	64	59 (47-72)
Triple PPI-A-M	68 (2.2%)	61	59 (46-72)	59	59 (46-73)
Overall	3,161 (100%)	2,964	73 (71-74)	2,875	74 (72-76)

mITT, modified intention-to-treat; PP, per-protocol; N, total number of patients analysed; 95% CI - confidence interval; PPI, Proton Pump Inhibitor; A, amoxicillin; B, bismuth; C, clarithromycin; D, doxycycline; L, levofloxacin; M, metronidazole; Tc, tetracycline; R, rifabutin; *, achieved over 90% effectiveness when optimised (high-dose PPIs and 14-days length).

Table 1. Effectiveness of the most frequently prescribed empirical therapies on third and subsequent treatment lines.

Conclusion: Empirical rescue treatments in third and subsequent lines obtain, in general, suboptimal eradication rates in Europe; however, bismuth quadruple therapy as single-capsule obtained encouraging results. Only the optimised bismuth quadruple therapy achieved $\geq 90\%$ effectiveness.

DEVELOPMENT OF A QUESTIONNAIRE FOR 'INABILITY TO BELCH' AND FIRST EVALUATION AGAINST HIGH RESOLUTION IMPEDANCE MANOMETRY WITH BELCH PROVOCATION TEST

K. Raymenants¹, T. Guedens¹, J. Arts^{1,2}, Y. Kjöller³, H. Van Gucht³, M. Mukherjee³, N. Rommel⁴, T. Vanuytsel¹, J. Tack¹
¹UZ Leuven, KU Leuven, Translational Research Center for Gastrointestinal Disorders, Department of Neurogastroenterology and Motility, Leuven, Belgium, ²AZ Sint-Lucas Brugge, Gastroenterology and Hepatology, Brugge, Belgium, ³UZ Leuven, Gastroenterology and Hepatology, Leuven, Belgium, ⁴University of Leuven, Department of Neurosciences, Leuven, Belgium

Contact E-Mail Address: karlienraymenants@gmail.com

Introduction: 'Inability to Belch', also called retrograde cricopharyngeal dysfunction (R-CPD), is a syndrome characterized by inability or impaired ability to belch, gurgling noises from the chest or lower neck, thoracic or abdominal pain, bloating and flatulence (1). Although awareness of the disorder is increasing, little is known about its cause, characteristics or epidemiology.

Besides recognition of typical symptoms, high resolution impedance manometry (HRIM) is increasingly used to confirm the diagnosis in suspected cases (2, 3).

Aims & Methods: Our aim was to design a diagnostic questionnaire based on the cardinal symptoms, and to validate this questionnaire against the only available objective diagnostic tool at present, i.e. HRIM with belch provocation test (sparkling water) (2, 3).

The questionnaire was developed based on medical history taking of patients that presented to our center with 'inability to belch' (4). Fifteen symptoms were included: inability to belch, gurgling noises, thoracic pain, abdominal pain, nausea, fullness, early satiety, bloating, flatulence, heartburn, regurgitation, frequent or painful hiccups, dysphagia, and difficulty to vomit.

These were questioned for frequency, severity, bothersomeness and the trigger or timing at which they occurred. A first draft of the questionnaire was evaluated in a cognitive debriefing of the first three R-CPD patients, after which some clarifying changes were made.

Subsequently, the questionnaire was filled out during HRIM prospectively by R-CPD and control patients, each of whom underwent belch provocation test as described by our group (3).

Wilcoxon signed rank test was used to compare between groups. A logistic model was used to compute probabilities with their 95% confidence interval (CI).

Results: The questionnaire was completed by 17 patients reporting inability to belch, and 47 control patients, during HRIM with belch provocation test. In 13 out of 17 patients (sensitivity 76%, positive likelihood ratio of HRIM: 8.44), R-CPD was confirmed with typical findings on HRIM. The indication for HRIM in control patients was GERD (n=27), dysphagia (n=9), chest pain (n=3), known achalasia (n=2), belching (n=1), globus (n=1) and dyspepsia (n=1). In the control patient group, 4 patients were excluded from further analysis because of abnormalities on HRIM similar to R-CPD (specificity 91%, negative likelihood ratio: 0.26).

Using HRIM as a gold standard, we identified the following questions that were significantly different in R-CPD patients vs. controls: frequency of inability to belch ($p < 0.001$, probability of abnormal HRIM when present: 0.6000 CI 0.380:0.786), gurgling noises ($p = 0.0019$, probability when present 0.4000, CI 0.230:0.597), and dysphagia ($p = 0.003$, probability when present 0.065, CI 0.016:0.022). Even though these symptoms were often

present in R-CPD, chest pain, abdominal pain, nausea, fullness, early satiety, bloating, heartburn, regurgitation, hiccups and vomiting did not differ significantly between both patient groups.

Conclusion: We designed a diagnostic questionnaire to help identifying R-CPD. Based on a comparison between R-CPD patients with a control population with a variety of upper motility disorders, the presence of 'inability to belch', gurgling noises; and the absence of dysphagia were significantly different between R-CPD patients and controls.

Pending further validation, this questionnaire provides a basis for developing a scoring system for patients with 'inability to belch' and it can be used to explore the epidemiology of this peculiar syndrome.

Introduction: Globus pharyngeus is one of the more common Disorder of Gut Brain Interaction (DGBIs). The pathophysiological mechanisms of DGBIs are complex. However, data considering possible cause of globus pharyngeus are scarce. Accumulating evidence indicates that autonomic dysregulation contributes to DGBI but whether this is true for globus is still unknown. The symptoms are often triggered by stress associated with sympathetic overexcitation, however, the mechanisms of sympathetically linked regulation in these disorders, especially in response to stress are incompletely understood.

Aims & Methods: The aim of this study was to assess potential changes of cognitive stress-related sympathetic regulation of different effector responses (skin conductance and alpha-adrenergic vasomotor activity) in patients suffering from globus pharyngeus. Studied population included 15 patients diagnosed with globus and 12 sex- and age-matched healthy controls. All patients were diagnosed according to ROME IV criteria for Dis-

orders of gut brain interaction. Continuous electrodermal activity (EDA) was recorded with sampling frequency of 256 Hz (required by hardware) (FlexComp Infinity Biofeedback, Thought Technology, Canada). The EDA signal was monitored by two dry, Ag-AgCl, bipolar electrodes placed on the middle phalanges of two fingers on the left (non-dominant) hand, and continuous “beat-to-beat” blood pressure (BP) was recorded using Finometer MIDI (FMS, Netherlands) during complex stress response: rest - mental arithmetic test - recovery. Each period lasted 5 minutes. Evaluated parameters: 1) spectral power in low-frequency band of systolic BP variability (LF-SBP) reflecting sympathetic alpha-adrenergic stimulation of vascular smooth muscles, 2) skin conductance level (SCL) calculated as a mean of tonic EDA reflecting sympathetic cholinergic regulation and emotional arousal in response to cognitive stress. Moreover, reactivity of both parameters was calculated.

Results: LF-SBP (reflecting sympathetic function) was normal at baseline, but significantly increased in response to mental arithmetic test in globus group compared to controls ($p < 0.001$), but in recovery phase LF-SBP parameter was without significant between-group changes. Surprisingly, no differences were found in SCL parameter during complex stress response. Reactivity of both parameters was similar and without significant changes.

Conclusion: Our results revealed significantly increased LF-SBP indicating alpha-adrenergic vasomotor overactivity during cognitive stressor associated with a return to basal values in patients with globus pharyngeus compared to controls. In contrast, EDA was without between-group changes during all phases of stress response which may point to remaining emotional and sympathetic arousal in patients with globus pharyngeus. These findings revealing subtle and discrete abnormalities in alpha-adrenergic sympathetic regulatory network evoked only by cognitive stress and can contribute to clarifying the pathomechanisms and psychophysiological pathways leading to sympathetic and emotional dysregulation in patients with globus pharyngeus. We believe that this represents a fundamental step for personalized and specific non-invasive therapy in patients with globus pharyngeus such as biofeedback.

MANAGEMENT IN PRIMARY CARE OF PATIENTS UNDER 50 PRESENTING WITH SYMPTOMS OF FOOD BOLUS OBSTRUCTION OR DYSPHAGIA

N. Umar¹, C. Turnbull², R. Jazrawi³, N. Trudgill¹

¹Sandwell and West Birmingham Hospitals NHS Trust, Gastroenterology, West Bromwich, United Kingdom, ²Dr. Falk Pharma GmbH, Bourne End, United Kingdom, ³Dr. Falk Pharma UK Ltd., Medical, Bucks, United Kingdom

Contact E-Mail Address: nosheen.umar@nhs.net

Introduction: Symptoms of dysphagia are common in the community and younger patients may not be referred for endoscopy if symptoms are not suggestive of malignancy. We have examined the management of patients under 50 with dysphagia in primary care.

Aims & Methods: Retrospective study using primary care data (Clinical Practice Research Datalink AURUM) linked to hospital admission data (Hospital Episode Statistics) between 2010 and 2022. All patients 18-50 years presenting in primary care with dysphagia or food bolus obstruction were studied. Patients with upper gastrointestinal (UGI) cancers were excluded. Referral rates for OGD and biopsy and proton pump inhibitor (PPI) prescription were examined. Patient level factors associated with referral rates within 1 year of symptom onset and PPI prescription within 30 days of a symptom record in primary care were studied using Robust Poisson regression models.

Results: Of 59,878 symptomatic patients, 98.2% had dysphagia and 1.8% had food bolus obstruction (median age 39 (IQR 30-46) years; 57.7% female). 7871 (3.2%) patients with UGI cancer were excluded. Of 696 diagnosed eosinophilic oesophagitis patients (1.2%), 92% presented with dysphagia and 8% with food bolus obstruction. 12,341 (21%) of patients with dysphagia and 248 (23.6%) of patients with FBO were not referred for endoscopy or gastroenterology assessment and simply prescribed a PPI. Factors associated with not being referred included: younger age adjusted relative risk 0.62, 95% CI 0.61-0.64, comparing 47-50 years (4th quartile) to 18-30 (1st quartile); black ethnicity 1.06, 1.03-1.09; and PPI prescription 1.09, 1.08-1.11. Factors associated with PPI prescription after dysphagia presentation included: increasing age adjusted relative risk 1.66, 1.60-1.73, comparing 47-50 years (4th quartile) to 18-30 (1st quartile); increasing deprivation 1.05, 1.01-1.10; smoking 1.05, 1.01-1.08; obesity 1.22, 1.18-1.26; and asthma 1.13, 1.10-1.16.

Factors associated with not being referred for food bolus obstruction included: black ethnicity 1.35, 1.16-1.58; a history of atopy 1.20, 1.08-1.32; and PPI prescription 1.43, 1.31-1.56. Endoscopy was performed in only 33% of patients with a FBO presentation in primary care, of which 62% had oesophageal biopsies taken.

Conclusion: In patients <50 presenting in primary care, 66% of food bolus obstruction and 67% of dysphagia patients were not referred for endoscopy despite risk factors for eosinophilic oesophagitis including atopy or asthma, representing a missed opportunity to diagnose eosinophilic oesophagitis. 24% of food bolus obstruction and 21% of dysphagia patients were just treated with a PPI without further investigation.

THE CHARACTERISTICS OF RAPID DEVELOPMENT ACHALASIA COMPARED TO LONGSTANDING ACHALASIA

A. Kurosugi¹, T. Matsumura¹, M. Sonoda¹, S. Takahashi¹, T. Kaneko¹, K. Okimoto¹, J. Kato¹, N. Kato¹

¹Chiba University Hospital, Department of Gastroenterology, Chiba, Japan

Contact E-Mail Address: akanekurosugi1125@chiba-u.jp

Introduction: Achalasia is an esophageal motility disorder associated with impaired relaxation and peristalsis of the lower esophageal sphincter (LES). Although it has been reported to be associated with autoimmune diseases, viral infections, and eosinophilic esophagitis, the cause has not yet been elucidated. The course of the achalasia is also unknown. Although it was thought to be a longstanding disease, the existence of rapid development achalasia associated with SARS-CoV-2 infection has been reported recently [1][2]. This suggests that the progression pattern may be different depending on its underlying cause.

Aims & Methods: The aim of this study was to investigate the characteristics of the development of achalasia to find new insights into the cause and course of the disease. A total of 148 patients diagnosed with achalasia by high-resolution manometry (HRM) were included in this study. Questionnaires and medical records were reviewed to assess initial symptoms, progression patterns, and comorbidities. The relationships between HRM results and progression way of symptoms were also investigated. Rapid development was defined as a case in which a progressive course within few weeks was clearly answered.

Results: The type of achalasia was Type I in 79 cases, Type II in 56 cases, and Type III in 13 cases. Median age at onset was 45 (range 32-64), median age of diagnosis was 53 (range 40-72), and sex ratio (M:F) was 73:75. The mode of onset of symptoms was rapid development in 38 patients (25.7%), longstanding in 92 (62.2%), and unknown in 18 (12.1%). Among

the rapid development cases, three cases presented anhidrosis at the same time, which was significantly more than longstanding type (8% vs 0%, $P=0.02$, Fisher's exact test). Two cases of anhidrosis in this study were diagnosed as autoimmune autonomic ganglionopathy in which viral infection suggested involvement [3]. No significant differences were observed in progression patterns, resting LES pressure or IRP.

Conclusion: Achalasia may exhibit either rapid development or longstanding progression. Unlike longstanding cases, rapid development cases exhibited potential associations with anhidrosis in some cases. Although further case accumulation is needed, the results suggest that rapid growth achalasia may have a distinctive background such as anhidrosis compared to longstanding achalasia.

EVALUATION OF DIET AND EATING HABITS IN PATIENTS WITH ESOPHAGEAL ACHALASIA

A. Cesarini¹, G. Scalese¹, E. Ribichini¹, C. Mocci¹, D. Badiali¹

¹Sapienza University, Departement of Traslational and Precision Medicine, Rome, Italy

Contact E-Mail Address: chiaramocci94@gmail.com

Introduction: Esophageal Achalasia (EA) is a rare esophageal motility disorder, characterized by impaired peristalsis and incomplete relaxation of the Lower Esophageal Sphincter (LES) in response to swallowing. Key symptoms of the disease include dysphagia, food regurgitation, and retrosternal pain, significantly impacting the quality of life (QoL) and often leading patients to restrict their food intake. Consequently, EA patients often adopt self-managed dietary practices that may result in nutritional imbalances and deficiencies, given the lack of specific dietary guidelines.

Aims & Methods: This retrospective study aimed to describe and evaluate the dietary patterns, eating habits, and nutritional status of achalasic patients. Additionally, the secondary aim was to explore potential associations between food rheology and symptomatology. Patients with a manometric diagnosis of EA were recruited from our outpatient gastrointestinal pathophysiology center. Disease severity was assessed with Eckardt Symptoms Score (ESS), symptoms were evaluated with Modular Questionnaire Roma IV and QoL with the MD Anderson Dysphagia Inventory (MDADI). The MDADI outcomes were stratified into severe, moderate, mild and not perceived disability. Patients also filled out a food diary for 15 days, recording ingested food for each meal and symptoms onset. Estimated caloric intake and macronutrient composition were compared to those recommended by the Italian Society of Human Nutrition (SINU).

Results: Forty-three achalasic patients were included (M 24, F 19, mean age 56.7 ± 15.8 yrs). The median BMI was 23.7 (18.8-32.2), 34 patients (79%) had an active disease (ESS ≥ 3). Most patients reported mild to moderate disability (respectively 42% and 35%), while 21% reported severe disability and 2% perceived no disability. Disease activity, measured by ESS, strongly correlated with perceived disability ($r=0.59$; $p<0.0001$), while no significant correlation was found between ESS and BMI. The diary analysis showed a mean caloric intake of 1572±373 kcal versus the estimated needs of 2293,71±374 kcal based on anthropometric parameters

and physical activity, resulting in a mean caloric deficit of 720 ± 416 kcal ($p<0.0001$). Macronutrient analysis also reported an unbalanced distribution: carbohydrates 43.3%±7.3 vs recommended 55-59%, protein 18.2%±4.5 vs 15-18%, total fat 37.6%±7.7 vs 26-27% and fibre 14g±5.2 vs 25-30g. Solid food caused significantly more symptoms than semiliquid and liquid ones: dysphagia (35.5% vs 3.5% vs 5.7%, $p<0.0001$), chest pain (10% vs 12.1% vs 0.2%, $p<0.0001$), regurgitation (8.9% vs 1.4% vs 1.9%, $p=0.001$), cough (5% vs 0.2% vs 0.6%, $p=0.0002$). Bread, pasta, and pizza (50-60%), fresh fruit (44%), lean meat (39.5%), crackers, snacks, and vegetables (30-35%) were the most commonly reported triggers of dysphagia. Additionally, 60% of patients reported worsened symptoms with cold foods, while 53% reported improvement with hot foods.

Conclusion: This study underscores the significant impact of EA on QoL, influenced by disease activity. Achalasic patients tend to modify their diets to minimize symptoms, favoring easily swallowable soft and fatty foods while reducing intake of solid foods rich in carbohydrates and fiber. Thus, comprehensive nutritional assessment is strongly recommended for EA patients to mitigate dietary imbalances and manage possible deficiencies promptly.

Disclosure: Nothing to disclose.

COMPARATIVE LONG-TERM OUTCOMES OF PERORAL ENDOSCOPIC MYOTOMY IN TREATMENT-NAÏVE ACHALASIA VERSUS PATIENTS WITH PRIOR SURGICAL INTERVENTIONS

M. Ito¹, N. Tada¹, H. Matsui¹, A. Dobashi¹, T. Masuda², F. Yano², K. Sumiyama¹

¹The Jikei University School of Medicine, Endoscopy, Tokyo, Japan,

²The Jikei University School of Medicine, Surgery, Tokyo, Japan

Contact E-Mail Address: mamoru.ito1222@gmail.com

Introduction: Peroral endoscopic myotomy (POEM) has become a standard endoscopic treatment for patients with achalasia, with many studies reporting on its long-term effectiveness. However, the impact of a patient's previous surgical history on the long-term outcomes of POEM remains unknown.

Aims & Methods: This study aims to compare the long-term efficacy of POEM in achalasia patients with and without prior surgical interventions. A single center, retrospective review was conducted on achalasia patients who underwent POEM between January 2016 to December 2020. Clinical, demographic, radiographic, endoscopic, and manometric data were collected. Patients with less than two years of follow-up without noted failure were excluded. The analysis compared outcomes between first-time POEM patients (naïve POEM) and those undergoing POEM following failed surgical treatments (redo POEM). The primary outcome was the clinical success rate, defined as an Eckardt Score of 3 or less at final follow-up and no need for additional interventions. Secondary endpoints included the prevalence of postoperative gastroesophageal reflux disease (GORD), the necessity for acid suppression medications, and additional interventions for achalasia.

Results: Data were collected on 47 naïve POEM and 26 redo POEM patients. After excluding 17 naïve POEM patients and 8 redo POEM patients who did not meet the criteria for long-term follow-up, a total of 30 naïve POEM patients and 18 redo POEM patients were analyzed. In the redo POEM group, 77.8% (14/18) of the patients underwent Heller myotomy with Dor fundoplication, while the surgical details for the remaining patients were unknown. The median length of symptoms was 5 (IQR 3-10) years for naïve patients and 6 (IQR 1.2-17.5) years for redo patients ($p=0.29$). According to the Chicago classification v4.0, the achalasia subtypes in the naïve POEM group were Type I in 9 patients (30%), Type II in

12 (40%), Type III in 3 (10%), and other types in 6 (20%). For the redo POEM group, subtypes were Type I in 9 patients (50%), Type III in 2 (11.1%), and unspecified in 7 (38.9%). Barium esophagram revealed no significant differences in the maximum diameter between the groups (naïve POEM 45.8 ± 21.4 mm vs. redo POEM 44.9 ± 15.4 mm, $p=0.89$). Long-term success rates were 76.7% (23/30) in naïve POEM and 83.3% (15/18) in redo POEM, with no significant difference between the groups ($p=0.72$). Postoperative GORD was noted in 63.3% (19/30) in the naïve POEM versus 67% (12/18) in the redo POEM ($p=0.06$), with newly prescribed acid suppression medication in 23.3% (7/18) and 55.6% (10/18), respectively ($p=0.02$). Additional interventions for achalasia were required in 10% (3/30) in the naïve POEM versus 11.1% (2/18) in the redo POEM, with no significant difference between the groups ($p=1.0$). In the naïve POEM group, one patient required a second POEM, another was hospitalized due to achalasia recurrence, and a third underwent Heller myotomy with Dor fundoplication. In the redo POEM group, one patient underwent endoscopic balloon dilatation, and another required esophagectomy.

Conclusion: POEM is an effective long-term treatment for achalasia, demonstrating similar success rates in patients undergoing either their first or redo POEM procedures. The overall efficacy and safety profiles support POEM as a recommended treatment for managing achalasia regardless of prior surgical treatment failures.

Disclosure: Nothing to disclose.

Introduction: Per-oral endoscopic myotomy (POEM) has been widely employed as a treatment for esophageal motility disorders since 2008, exhibiting an efficacy rate of approximately 80-90% and a safety rate of 90%. Nevertheless, approximately 10% of patients remain symptomatic after treatment, with limited data available on second-line strategies. Our aim was to determine the validity of redoPOEM as a second line therapy after POEM failure.

Aims & Methods: We conducted a retrospective multicenter study involving 15 French expert centers, including all patients who underwent redoPOEM up to the end of September 2023. Patients were classified as experiencing primary failure if their Eckardt score exceeded 3 at 3 months post-procedure, and as experiencing secondary failure if their Eckardt score exceeded 3 at the last follow-up or if additional treatment was necessary. Safety was assessed using the AGREE classification, with events of grade II or higher considered significant.

Results: Ninety-one patients were included in the study, 44% were female, the average age was 54.6 ± 18.0 years. Patients were followed for a mean duration of 22 months (range 3,5 – 69,5 months). The mean Eckardt score before redoPOEM was 5.8 ± 2.0 . No technical failure was reported. At the 3-month follow-up, 79% of patients had achieved clinical success, with an average Eckardt score of 2.05 ± 2.0 . Long-term success was observed in 60.5% of all patients, and among those who had achieved clinical success at the 3-month mark, the long-term success rate was 77%. Additionally, 25% of the patients required a complementary treatment, such as botulinum toxin injections, endoscopic dilation or Heller myotomy. A low Eckardt score before redoPOEM was associated with clinical success at the 3-month follow-up in univariate analysis, whereas an Eckardt score of 5 or higher before redoPOEM appeared to be a risk factor for primary failure. Multivariate analysis did not show any predictive factors of failure. The safety rate was 90%, with no reported deaths within one month following the procedure. Nine patients experienced grade II or higher adverse event: four patients were treated with antibiotics for pneumonia or mucosal breach without further complications, while four others underwent a new endoscopy due to mucosal breach, with covered esophageal stents or hemostatic clips used to manage the situation. One patient experienced multiorgan failure.

Conclusion: RedoPOEM proves to be an effective strategy for managing patients who experience primary failure or symptomatic relapse following a POEM. It demonstrates promising efficacy and safety outcomes, supported by the largest cohort reported to date for redoPOEM. Further research is warranted to compare redoPOEM with Heller myotomy and endoscopic dilation as second-line treatments for esophageal motility disorders.

Disclosure: Nothing to disclose.

Orsola-Malpighi University Hospital, Department of Medical and Surgical Sciences, Bologna, Italy

Contact E-Mail Address: g.dellanna93@gmail.com

Introduction: Endoscopy is the first-line approach for managing Zenker's Diverticulum (ZD). Various endoscopic techniques, each with its own advantages and limitations, have been described. We have proposed a new technique, which we have named Submucosal Injection-Guided septomyotomy (SING technique).

Aims & Methods: The performance of SING technique was evaluated in a prospective observational cohort of patients with ZD who underwent the

procedure at two Italian hospitals: San Raffaele Hospital (Milan, Italy) and San Giovanni Bosco Hospital (Turin, Italy).

SING technique involves a classic septotomy, which consists of a mucosal incision with a Hook-Knife in the middle of the septum and a cricopharyngeal myotomy for all the length of the Zenker's Diverticulum and beyond 10 mm into the esophageal proper muscular layer. The novelty of the technique lies in the submucosal injection during the septomyotomy on both the esophageal and diverticular sides, which helps to better delineate the muscular layer and guide the complete myotomy, without the need for bilateral submucosal tunnelling.

Clinical success (CS) was defined as a Dakkak and Bennet Dysphagia Score (DBDS) of ≤ 1 and a Kothari-Haber Score (KHS) of < 2 at 3 months. Recurrence was defined as an increase in DBDS of > 1 after achieving CS or a KHS of ≥ 2 after CS. Follow-up included clinical evaluations at 3 and 6 months, and then annually. Adverse Events (AEs) are classified according to the AGREE Classification.

Results: 42 patients with ZD underwent SING technique between March 2021 and January 2024 (median age 74 [IQR 67-80], 66.7% males, BMI 24.6 [IQR 21-27]). The median diverticula depth was 30mm (IQR 25-45) with a median septum length of 20mm (IQR 14-30). Median KHS at diagnosis was 4 (IQR 4-6), dysphagia for solids (42.9%) was the most common symptom, with a median symptom duration of 12 months (IQR 6-24). While a technical success rate was observed in all cases (42/42, 100%), a clinical success rate was observed in 40/42 patients (95.2%). In the 2/42 (4.8%) cases of clinical failure, endoscopic evaluation revealed the presence of a minimal residual muscular septum successfully treated with septomyotomy. Median procedural time was 34 minutes (IQR 29-60), with a hospital stay of 2 days (IQR 2-2). No AEs were recorded. After a median follow-up of 370 days (IQR 297-747), no cases of symptom recurrence were recorded.

Conclusion: SING technique is a safe and effective technique for the endoscopic treatment of ZD. It improves and enhances the efficacy of traditional endoscopic septotomy and can also be utilized as rescue therapy.

Disclosure: Nothing to disclose.

COMPLETE MYOTOMY OF THE CRICOPHARYNGEAL MUSCLE WITH THE 'CLUTCH CUTTER' SCISSORS: THE BENEFIT OF Z POEM WITHOUT THE ASSOCIATED MORBIDITY IN SYMPTOMATIC ZENKER'S DIVERTICULA

M. Harb¹, J.-B. Danset¹, C. Medlij¹, O. Marty¹, D. Levoir¹, B. El Khoury¹, C. Souaid¹, Y. Le Baleur¹

¹Hospital Saint Joseph de Paris, Paris, France

Contact E-Mail Address: marc_harb@hotmail.com

Introduction: Several therapeutic modalities, including surgery, rigid and flexible endoscopy, have been described for the management of symptomatic Zenker's diverticulum (ZD). Symptom relief such as dysphagia and regurgitation constitute the primary goal of treatment. The ESGE (European Society of Gastrointestinal Endoscopy) recommends as first-line treatment the performance of a septotomy, which has a higher safety profile compared to Z POEM (Zenker's Peroral Endoscopic Myotomy). Septotomy is most commonly performed using a dissection knife or a needle knife, stopping the section 5 mm from the bottom of the diverticulum, leaving muscle fibers intact, which may contribute to some of the recurrences in the medium and long term. The aim of this retrospective study was to evaluate the safety and efficacy at 12 months of complete myotomy of the diverticular septum using a dissection scissor.

Aims & Methods: A septotomy with sectioning of the cricopharyngeal muscle fibers was performed in 43 patients presenting with a symptomatic Zenker's diverticulum of the upper third of the esophagus using the following technique: After oro-tracheal intubation in a patient lying

supine, gastroscopy with a single-channel gastroscope equipped with a transparent hood was performed. Once the hood was positioned over the septum, an incision with a clutch cutter (Fujifilm) was made at two points on the diverticular wall, 5 mm apart, extending 2 mm into the mucosa and submucosa.

The next step involved avulsion of the mucosal and submucosal hood using a 10 mm diathermic loop by mucosectomy without injection to expose the cricopharyngeal muscle. Subsequently, complete sectioning of all muscle fibers using the clutch cutter under traction, followed by closure of the defect along its entire height using clips, was performed.

The symptoms were analyzed before the intervention as well as at 3, 6 months, and 1-year post-intervention using a comprehensive questionnaire with each patient serving as their own control before and after the procedure.

The following data were collected: peri- and post-procedural complications (hemorrhage, perforation, infection, others), procedure duration, immediate technical success, and clinical success at 3 months, 6 months, and 1 year.

Results: The average size of the Zenker's diverticulum was 25.6 mm, and the average procedure duration was 48 minutes.

No peri- or post-procedural complications were observed, although one patient experienced an injury to the piriform sinus. Patient follow-up was conducted at 3, 6, and 12 months post-intervention. During follow-up consultations, patients assessed the improvement of their symptoms as a percentage.

At 3 months, 92% of patients experienced a 100% improvement in their preoperative symptoms. By 6 months, 94% of patients reported a 100% improvement, which further increased to 97% at 12 months.

This series, the largest ever reported of complete cricopharyngeal myotomy using the Clutch cutter with complete closure of the defect, achieves an equivalent of "open" Z POEM without detachment of the cervical or mediastinal adipose spaces, with very low morbidity and a recurrence rate lower than that of classical septotomy.

Conclusion: The technique of complete cricopharyngeal muscle sectioning using the Clutch Cutter dissection tool is safe, effective, and associated with low morbidity, along with a very low recurrence rate at one year. It could potentially be considered as a first-line treatment for symptomatic Zenker's diverticula in patients who have not undergone prior treatment.

Disclosure: I can affirm that there is no conflict of interest associated with the study I conducted.

REPEAT PERORAL ENDOSCOPIC MYOTOMY: TECHNICAL DIFFICULTY AND RISK FACTORS

L. Ma¹, Z.-Q. Liu¹, Q.-L. Li¹, P.-H. Zhou¹

¹Zhongshan Hospital, Fudan University, Endoscopy Center and Endoscopy Research Institute, Shanghai, China

Contact E-Mail Address: maly14@fudan.edu.cn

Background and aims: Repeat peroral endoscopic myotomy (Re-POEM) appeared to be a promising salvage option for patients with persistent/recurrent symptoms after initial POEM, but it may be more.

Aims & Methods: Between July 2012 and October 2023, 158 achalasia patients underwent Re-POEM were retrospectively enrolled in this study. Another 2978 patients without prior myotomy were selected for naïve POEM. After propensity score matching (PSM), procedure-related parameters were compared between the two groups. Univariable and multivariable analyses were performed to reveal risk factors for difficult Re-POEM.

Results: With similar baseline characteristics between two groups after PSM, the procedure time was comparable between Re-POEM and naïve

POEM groups (61.4±27.0 vs. 59.3±29.9, $p=0.496$). The Re-POEM group showed shorter esophageal myotomy length (7.0±2.1 vs. 8.2±1.1, $p<0.001$) and longer gastric myotomy length (2.3±0.6 vs. 2.1±0.4, $p=0.017$), compared with the naïve POEM group. Mucosal injury in Re-POEM group was slightly higher, which was not statistically significant (20.3% vs. 13.9%, $p=0.135$). No differences were found in the incidence of gas-related adverse events (AEs), major AEs, and technical difficulty. Multivariate analysis determined mucosal edema (OR=4.942, 95% CI, 1.554-15.714, $p=0.007$) and submucosal fibrosis (OR=3.817, 95% CI, 1.333-10.931, $p=0.013$) to be independent risk factors for difficult Re-POEM.

Conclusion: Re-POEM appears safe and feasible as a salvage option after initial POEM failure, with comparable procedure duration, incidence of AEs and technical difficulty to naïve POEM. Mucosal edema and submucosal fibrosis were associated with difficult Re-POEM.

Disclosure: Nothing to disclose.

Introduction: Decreased vagus nerve activity and increased inflammatory immune cells are observed in ulcerative colitis (UC) (1, 2). Due to its anti-inflammatory and protective properties, vagus nerve stimulation (VNS) has garnered attention for UC therapy (3). Non-invasive transcutaneous auricular vagus nerve stimulation (NitaVNS), devoid of the side effects associated with invasive techniques, demonstrates protective anti-inflammatory effects in our mouse UC-like model of colitis (4), although the specific cellular mechanisms remain unclear.

Aims & Methods: To evaluate the effects of NitaVNS on the distribution of granulocytes, macrophages, natural killer (NK) cells, and CD4⁺ and CD8⁺ T cells in the colon tissue, spleen, and mesenteric lymph nodes of a UC-like colitis mouse model, NitaVNS was administered to C57BL/6 male mice daily for 10 min, beginning one day before colitis induction with 5% dextran sulfate sodium for 5 days in water (the control group received regular water). This continued until the end of the study, with no stimulation in sham mice. The daily disease activity index (DAI) was evaluated along with distal macroscopic scores at the time of sacrifice. The frequencies of granulocytes (Ly6G), macrophages (F4/80), NK cells (NK1.1), CD4⁺ T cells (CD3, CD4), and CD8⁺ T cells (CD3, CD8) were analyzed in the cecum, proximal, mid and distal colon, spleen, and mesenteric lymph nodes (MLNs) using flow cytometry.

Results: NitaVNS in colitic mice significantly improved the DAI and macroscopic scores related to rectal bleeding, colon bleeding, fecal consistency loss, and shortened colon length compared to sham-stimulated colitic mice. In contrast, no changes were observed in the non-colitic mice. While NitaVNS did not alter the frequency of Ly6G⁺ cells in the cecum, mid/distal colon, and MLNs, it significantly decreased the positivity of these cells in the proximal colon and spleen of mice with colitis without affecting non-colitic mice. NitaVNS significantly decreased the frequency of F4/80⁺ cells in the mid-colon but did not influence these cells in the cecum, proximal and distal colon, spleen, or MLNs. In colitic conditions, NitaVNS significantly increased NK cell frequency in the spleen without affecting non-colitic mice. Moreover, NitaVNS did not alter the frequency of NK cells in the colon or MLNs in colitic or non-colitic mice. Additionally, NitaVNS did not induce changes in CD4⁺ and CD8⁺ T cell distribution in the colon tissue, spleen, or mesenteric lymph nodes of colitic and non-colitic mice.

Conclusion: These results suggest that NitaVNS could potentially reduce inflammation in colitic mice, locally and systemically, by decreasing the frequency of granulocytes in the colon and spleen and colonic macrophages. Additionally, NitaVNS increased the number of splenic NK cells, potentially contributing to its systemic effects. These findings indicate promising therapeutic potential for NitaVNS.

Introduction: Patient-derived organoids represent a valuable tool to unravel disease- and patient-specific mechanisms in inflammatory bowel diseases (IBD). We previously showed that organoids from patients with ulcerative colitis (UC) lose their acute inflammatory phenotype, and consequently established an inflammatory mix to re-induce inflammation in undifferentiated intestinal organoids¹. However, inducing solely inflammation might not be sufficient to study IBD-specific pathways as, for example, endoplasmic reticulum (ER) stress has been shown a role in the pathogenesis of IBD, and targeting the ER protein folding homeostasis of epithelial cells could be a new treatment target².

Aims & Methods: To effectively use organoids as a pre-clinical model for IBD, there is a critical need to 1) enable prolonged exposure to preclinical compounds, in an inflammatory setting, to decipher their mechanism of action and 2) establish different disease phenotypes to study disease mechanisms. To this aim, we optimized two mixes tailored to induce either an inflammatory (INF) or ER stress-driven inflammatory phenotype in differentiated intestinal organoids. Intestinal organoid cultures, isolated from endoscopy-derived non-inflamed colonic biopsies of nine patients with UC were expanded, mechanically dissociated, followed by culturing in an human expansion media³ for two days. Next, the cultures were subjected to a differentiation media (human expansion media without the addition of WNT3a, nicotinamide and SB202190) for four consecutive days. On day six, organoids were exposed to either the differentiation media only, an INF mix (50 ng/ml TNF- α , 20 ng/ml IL-1 β , 1 μ g/ml Flagellin) or an ER stress mix (10 ng/ml TNF α , 20 ng/ml IL-1 β , 1 μ g/ml Flagellin, Tunicamycin 25ng/ml) for 48 hours in differentiation media. RNA was extracted and sequenced by Illumina Truseq mRNA (HiSeq4000). Differential gene expres-

sion and pathways were studied through DESeq2 and Ingenuity Pathway Analysis ($|\log_2FC| > 2$, FDR < 0.05).

Results: Transcriptomic analysis demonstrated a clear separation on principal component analysis of the untreated control and INF and ER mix exposure upon 48 hours of exposure. The INF mix exposure resulted in the upregulation of 324 and the downregulation of 148 genes compared to the untreated control, while the ER mix exposure resulted in 368 and 138 genes being up- and downregulated respectively compared to the untreated control. Inflammatory markers (CXCL1, CXCL2, CXCL11, IL1 β , IL8) were significantly upregulated following exposure to both the INF mix and the ER stress mix. However, only organoids challenged with the ER stress mix showed a strong upregulation of ER stress markers (PDIA4 HSP90B1, HSPA5, DDIT3, all within $|\log_2FC| > 2$). Ingenuity Pathways Analysis (IPA) of the contrast of the ER stress mix versus the INF mix highlighted the up-regulation of ER stress-related pathways including ATF6 (ATF6-alpha) activates chaperone genes and ATF4 activates genes in response to endoplasmic reticulum stress.

Conclusion: Exposure of UC patient-derived differentiated colonic organoids for 48 hours to either the INF mix or ER stress mix significantly upregulated INF markers, while ER stress markers only resulted in being significantly upregulated after exposure to the ER stress mix. IPA confirmed that the dysregulated genes were part of ER stress-related pathways. These results will facilitate the use of organoids to mimic an INF or ER stress phenotype and will promote their use to study pre-clinical compounds for prolonged exposures (48 hours) in a disease-representative IBD model.

Introduction: Inflammatory Bowel Diseases (IBD) are chronic inflammatory disorders characterized by alterations of acute relapses and remission. The past decades have brought substantial advances in the pharmacological management of IBD by a wide range of medicines. However, the sustained efficacy of the currently available anti-inflammatory therapies is still far from optimal. Therefore, the development of novel therapies represents a major unmet clinical need in this field. Recently, the enrichment of the coagulation pathway genes and among these, Plasminogen activator inhibitor 1 (PAI-1) was described in IBD, whereas PAI-1 emerged as a link between the epithelium and inflammation. Moreover, the genetic deletion of PAI-1 prevented the severity of experimental colitis in mice.

Aims & Methods: Based on these, we aimed to develop and test novel PAI-1 inhibitors for the treatment of IBD.

The novel, amino acid-based PAI-1 inhibitor, LDN-071 was synthesized by the A³SMO[®] platform. The inhibitory potential and cytotoxicity effects of the peptide were determined by *in vitro* assays. Acute and chronic colitis was induced in mice with DSS and 10 mg/bwkg LDN-071 was administered *per os*. The changes of body weight, spleen weight, and colon length were measured. Haematoxylin eosin (HE) and Periodic acid-Schiff (PAS) staining were performed for histology. ELISA and qRT-PCR measurements were applied to analyze the cytokine expressions. Hydroxyproline assay was used to quantify the mucosal collagen deposition. *In vivo*, the toxicity of LDN-071 was determined in mice. Human colon organoid and fibroblast (FB) cell cultures were generated from IBD patients and the effects of LDN-071 were observed.

Results: LDN-071 significantly inhibited PAI-1 *in vitro* without decreasing the cell viability in a concentration range of 1 μM–1 mM. In the acute mice model, the administration of 10 mg/bwkg LDN-071 in the DSS-treated mice prevented the body weight loss, the development of bloody diarrhea, the decrease of colon length, and the increase of the spleen weight, which were displayed by the DSS+vehicle-treated animals. The histological analysis of the colon revealed that DSS treatment induced severe transmural inflammation, ulceration, loss of crypt structures, and goblet

cell depletion. Importantly, all these parameters were significantly ameliorated by the administration of 10 mg/bwkg LDN-071 in the acute and chronic models as well. Additionally, mucosal gene and protein expressions of TNF-α, IL-1β, and IL-6 were significantly decreased by PAI-1 inhibition in the acute phase. Besides, the LDN-071 treatment significantly reduced the inflammation, epithelial erosion, and fibrosis caused by chronic administration of DSS. However, the collagen deposition was significantly lower in the PAI-1-inhibited DSS mice. Importantly, no signs of toxicity were observed in mice exposed to 100 mg/bwkg LDN-071 for 7 days. In our *in vitro* models, the PAI-1 inhibition reduced the protein level and gene expression of pro-inflammatory cytokines in human colon organoid of IBD patient. Moreover, the gene expression of fibrosis-related genes significantly decreased after the LDN-071 treatment in IBD patients-derived human FB cell culture.

Conclusion: Our results showed that LDN-071, a novel amino acid-based inhibitor of PAI-1, significantly ameliorated the severity of acute and chronic colitis in mice. However, the LDN-071 reduced the expression of inflammation- and fibrosis-related genes and proteins *in vitro* human models. We propose that the inhibition of PAI-1 could be a potential novel therapeutic strategy in IBD.

Disclosure: LDN-071 PAI-1 inhibitor is owned by Ladon Therapeutics Ltd.

Contact E-Mail Address: Thelma.Angeles@tevapharm.com

Introduction: Tumor necrosis factor-like ligand 1A (TL1A) has been implicated in numerous immune-mediated and fibrotic diseases, such as inflammatory bowel disease (IBD) and asthma, making it an ideal target for therapeutic intervention. TEV-48574 is a human IgG1 monoclonal antibody with a novel mechanism of action that preferentially inhibits binding of TL1A to the Death Receptor 3 (DR3), involved in proinflammatory signaling, with a greater potency compared to the Decoy Receptor (DcR3), which could preserve the natural homeostatic mechanism. TEV-48574 has been shown to reduce fibrosis, inflammation, and mortality in animal models of IBD and asthma.¹ A phase 1 first-in-human (FIH) study, comprised of a single ascending dose (SAD) and a multiple ascending dose (MAD) phase, assessed safety, tolerability, immunogenicity, pharmacodynamic and pharmacokinetics of TEV-48574 amongst healthy participants and those with asthma. It has also been assessed in a phase 2A uncontrolled T2 low/non T2 asthma proof-of-concept (POC) study, where results from an interim analysis met predefined futility criteria leading to early termination. TEV-48574 is in clinical development as a potential treatment for ulcerative colitis and Crohn's disease. This analysis aims to evaluate target engagement; free TL1A levels were measured in phase 1 and phase 2A TEV-48574 studies.

Aims & Methods: Free TL1A levels were measured using a ligand binding assay in the FIH and POC studies. In the FIH SAD phase, healthy participants were administered TEV-48574 as a single dose (1–1000 mg) or placebo by subcutaneous (SC) route. In the FIH MAD phase, mild asthmatic

patients were randomized to active (up to 2300 mg) or placebo SC treatment. The phase 2A POC study was a 16-week randomized, double-blind, parallel-group trial to evaluate the efficacy, tolerability, and safety of a single dose regimen of TEV-48574 compared to placebo.

Results: In the FIH study, following SAD and MAD administration, while unchanged in the placebo group, free TL1A levels showed a rapid reduction at the first analyzed time point (1 hour after dose) in the active treatment groups. The free TL1A levels in the MAD phase of the FIH study remained suppressed up to day 92 (63 days after last dose, pooled result for doses), despite extremely low remaining TEV-48574 concentrations. In the POC study, TEV-48574 resulted in reduction of free TL1A levels, sustained up to ~10 weeks after the last dose. An analysis of patients who received all doses showed a persistent pharmacodynamic effect, demonstrated by continued suppression of free TL1A despite decreasing concentrations of TEV-48574 after the last dose on day 98.

Conclusion: Target engagement was shown by a rapid and sustained TEV-48574-mediated suppression of free TL1A that persisted longer than the drug exposure. Given that TL1A has been implicated in the pathogenesis of immune-mediated and fibrotic diseases, such as IBD¹, the data here-in support further development of TEV-48574 in patients with ulcerative colitis and Crohn's disease.

ROSNILIMAB, A PD-1 AGONIST ANTIBODY IN CLINICAL DEVELOPMENT FOR ULCERATIVE COLITIS, REDUCES PATHOGENIC PD-1+ T CELLS AND INFLAMMATORY CYTOKINE SECRETION IN PATIENT BLOOD AND IN A MOUSE MODEL OF ULCERATIVE COLITIS

S. Parmley¹, C. Haines¹, P. Soroosh¹, R. Frank¹, M. Hsu¹, P. Brodsky¹, J. Michaels¹, P. Lizzul¹, M. Dahl¹

¹AnaptysBio, San Diego, United States of America

Contact E-Mail Address: mdahl@anaptysbio.com

Introduction: Checkpoint agonism represents a promising class of therapies for the treatment of autoimmune and inflammatory diseases, including ulcerative colitis (UC), where unmet needs persist. Engagement of checkpoint receptor PD-1 by its natural ligand PD-L1 is critical for regulation of T cells. Rosnilimab is an investigational PD-1 agonist IgG1 antibody designed to optimize inhibitory signaling through PD-1, does not block PD-1 binding to PD-L1, and depletes PD-1^{high} pathogenic T cells while agonizing remaining PD-1+ T cells. The percentages of PD-1+ T cells in the peripheral blood of moderate and severe UC patients are higher than in mild UC patients (1-4). Reduction of elevated PD-1^{high} Tph cells in both UC colon and peripheral blood correlates with remission (2). Therapeutic reduction of PD-1^{high} Tph cells and inflammatory cytokines from PD-1+ T cells, by depletion and agonism signaling together, has the potential to reduce overactive immune responses and induce remission.

Aims & Methods: The potency of the agonism and depletion mechanisms of rosnilimab was evaluated in vitro using peripheral blood mononuclear cells (PBMCs) from UC patients. Rosnilimab is a human IgG1 antibody with Fc effector function. A version of rosnilimab that lacks Fc effector function was generated by mutating the IgG1 Fc domain at L234A and L235A (LALA). PBMCs from UC patients were activated with anti-CD3 and anti-CD28, cultured for several days with rosnilimab IgG1, rosnilimab IgG1-LALA, or isotype control and analyzed for the number of PD-1+ T cells and levels of inflammatory cytokines. In addition, the therapeutic potential of depletion and agonism of pathogenic PD-1+ T cells was evaluated in a mouse model of UC using a surrogate of rosnilimab. The surrogate consists of the fab do-

mains of rosnilimab formatted with a mouse IgG2a Fc domain which enables immune cell depletion in mice. On Day 0, hPD1 CD4+CD45Rb+ T cells donor cells were adoptively transferred into Rag2^{-/-} recipients to elicit UC-like disease. Starting on Day 21, 10 mpk of isotype control mIgG2a, rosnilimab-mIgG2a, or control anti-mIL-12 p40 were dosed intraperitoneally twice weekly for 4 weeks. This model system allowed assessment of the therapeutic potential of depletion and agonism mechanisms of rosnilimab on hPD1+ T cells, with a depletion-enabled mouse IgG2a isotype, in the context of T cell-driven gut inflammation and pathology.

Results: In PBMCs from UC patients, at therapeutically relevant concentrations, rosnilimab IgG1 reduced PD-1^{high} T cells by 90%, while rosnilimab IgG1-LALA reduced PD-1^{high} T cells by 14%. Isotype control did not reduce T cells. Furthermore, rosnilimab IgG1 reduced secretion of inflammatory cytokines interferon gamma (IFN-γ) and CXCL13 compared to rosnilimab IgG1-LALA or isotype control. In the hPD-1 mouse model of UC, rosnilimab mIgG2a reduced body weight loss, colon pathology, IFN-γ and CXCL13 as assessed by spatial transcriptomics of the colon, and infiltration of hPD-1 CD4+ T cells into the colon as assessed by immunofluorescence, compared to isotype control. In addition, rosnilimab mIgG2a demonstrated efficacy comparable to anti-IL-12 p40 antibody treatment.

Conclusion: Rosnilimab, a PD-1 checkpoint agonist antibody, functions to reduce pathogenic PD-1+ T cells by both depletion and agonism. These in vivo and in vitro results are consistent with the mechanisms of depletion and agonism and support the strong rationale for evaluating the therapeutic potential of rosnilimab in an ongoing phase 2 study in UC (NCT06127043).

Introduction: Inflammatory cells and cytokines play an instrumental role in the pathogenesis and disease course of ulcerative colitis (UC) and are thus accepted therapeutic targets. NX-13 is a first-in-class, orally active, once-daily, gut-selective NLRX1 agonist in development for UC. NLRX1 is a mitochondrial associated protein with a novel, bimodal, immunometabolic mechanism which upregulates mitochondrial metabolism, reduces oxidative stress, and decreases pro-inflammatory cell differentiation and cytokine release broadly in mouse models of IBD¹. NX-13 was well tolerated and showed gut selectivity with low systemic drug exposure in Phase 1 studies reported previously^{2,3}. We now present data from the phase 1b study describing changes in tissue cytokine levels and related to clinical response.

Aims & Methods: In this double-blind phase 1B trial (NCT04862741)³, 36 patients with active UC (Total Mayo Score 4-10; Mayo endoscopic subscore 2-3) were randomly assigned to NX-13 250mg Immediate Release (IR), 500mg IR, 500mg Delayed Release (DR) or Placebo QD for 4 weeks. Protein levels of IFN γ , IL-10, IL-12(p40), IL-17, IL-4, IL-6, IL-8, MCP1, and TNF α in colonic tissue from NX-13 treated patients collected at screening (baseline) and week 4 of treatment were determined by Human Cytokine/Chemokine Panel – Immunology Multiplex Assay (Millipore Sigma) normalized to total protein concentrations. Patients from all NX-13 dose groups with paired baseline and week 4 samples (n=18) were included in this analysis. Mann-Whitney U testing was used for comparisons between responders (Resp) and non-responders (NR).

Results: Baseline cytokines levels were not different between Resp (change from baseline of at least -3, or -30% in total Mayo Score) and NR. NX-13 treatment resulted in a decrease of multiple proinflammatory cytokines at week 4 compared to baseline in most patients, and especially in Resp. compared to NR at week 4 (Table 1). Primarily, the reduction (% change from baseline) of Th1 cytokines IL-12(p40) and IFN γ was greater in NX-13 treated patients with clinical response compared to NR, resulting in significantly lower values in Resp compared to NR at the end of the 4-week study. Similarly, IL-6 also tended to be lower among Resp. after 4 weeks of treatment with NX-13. Additionally, Th2 cytokine IL-4 values were significantly lower after 4 weeks of NX-13 in patients in clinical response

compared to NR. Myeloid cell recruitment may also have been affected by cytokine changes induced by NX-13 as IL-8 and MCP levels were lower in clinical Resp. Reduced myeloid cell recruitment is consistent with higher levels of histologic remission in NX-13 treated patients³.

Cytokine	Primary Function	Mean % CFB (95% CI)			Mean Value Week 4 / End of Study (95% CI)		
		NR (n=7)	Resp (n=11)	p=	NR (n=7)	Resp (n=11)	p=
IL-12 (p40)	Th1	199 (-5.83-404)	-2.42 (-45.0-40.1)	0.03*	12.3 (1.2-23.5)	2.0 (1.2-2.9)	0.005**
IFN γ	Th1	1208 (-837-3253)	53.4 (-164-271)	0.004**	143.4 (-135.6-422.3)	6.3 (0.03-12.6)	0.01*
IL-6	Th1	3864 (-3044-10771)	63.7 (-126-253)	ns	120.4 (-17.5-258.4)	4.5 (1.4-7.6)	0.06#
IL-4	Th2	390 (-262-1041)	-13.7 (-61.9-34.4)	ns	31.0 (3.7-58.3)	3.7 (1.7-5.6)	0.01*
IL-8	Chemoattractant	1207 (-648-3063)	568 (-817-1954)	0.07#	204.3 (-0.1-408.6)	29.4 (7.4-51.4)	0.06#
MCP-1	Chemoattractant	968 (-769-2726)	7483 (-9258-24225)	ns	1684.2 (454.9-2913.4)	475.0 (145.6-804.4)	0.05#

CFB = Change from Baseline; NR= Clinical Non-Responder; Resp = Clinical Responder defined as CFB of at least -3, or -30% in total Mayo Score; **p $\leq$ 0.005, *p $\leq$ 0.05, #p $\leq$ 0.10. ns p $>$ 0.10 by Mann-Whitney U testing.

Conclusion: Broad changes in tissue cytokine expression were specifically observed in patients that responded to NX-13- after 4 weeks of treatment, compared to non-responders. These changes mirror those seen in preclinical mouse colitis models where a broad array of cytokines is reduced¹. The early onset of cytokine shifts associated with clinical response to NX-13 at week 4 is notable and will be assessed in the ongoing phase 2 NEXUS study in patients with moderate to severe UC (NCT05785715).

CHARACTERIZATION OF TWO NOVEL EXTENDED HALF-LIFE MONOCLONAL ANTIBODY DRUG CANDIDATES TARGETING TL1A FOR THE TREATMENT OF IBD

E. Zhu¹, D. Rios¹, J. Milligan¹, J. Ministro¹, B. Kang¹, J. Friedman², D. Nguyen², A. Spencer², M. Rose², J. Oh¹, H. Shaheen¹

Introduction: Tumor necrosis factor (TNF)-like ligand 1A (TL1A) mediates a broad spectrum of pro-inflammatory and fibrotic effects and is implicated in the pathogenesis of several immunologic disorders. A pathogenic role for TL1A in IBD is suggested by genetic association. Blockade of the interaction of TL1A with its cognate receptor, DR3, has been shown to ameliorate disease activity in patients with Crohn's disease (CD) and ulcerative colitis (UC). We have characterized SPY002-091 and SPY002-072, two novel TL1A-specific fully human IgG1 monoclonal antibodies (mAbs) with extended pharmacokinetic (PK) half-life. Both antibodies bind soluble and membrane-bound TL1A with high affinity and potentially inhibit TL1A-mediated signaling.

Aims & Methods: SPY002-091 and SPY002-072 were evaluated in multiple *in vitro* and *ex vivo* assays and compared to other anti-TL1A mAbs in clinical development (MK-7240, RG6631, and TEV-48574). Binding affinity to soluble TL1A was determined by surface plasmon resonance and binding to membrane-bound TL1A was confirmed by flow cytometry (FACS). Competitive blockade of TL1A binding to cell-surface DR3 was determined by FACS, and competition against the decoy receptor, DcR3, was evaluated by ELISA. The binding epitopes of SPY002-091 and SPY002-072 were determined using cryogenic electron microscopy (cryo-EM). TF-1 cell apoptosis and a primary human whole blood-based assay measuring IFN γ secretion were used to assess functional blockade of TL1A. Half-life extension was measured via pharmacokinetic analysis in cynomolgus monkeys given a single bolus of either SPY002 mAb by intravenous and/or subcutaneous (SC) administration.

Results: SPY002-091 and SPY002-072 each bind to distinct epitopes on TL1A with sub-nanomolar affinity but do not bind the related TNF super family proteins TNF, FasL, TRAIL, or LIGHT. Both antibodies bind soluble TL1A and TL1A expressed on the surface of human embryonic kidney (HEK) cells. Both antibodies potentially inhibit TL1A-induced apoptosis in human TF-1 cells and TL1A-induced secretion of IFN γ in human whole blood, with IC₅₀ values comparable to those of RG6631 and TEV-48574, and a substantially lower IC₅₀ than that of MK-7240.

In cynomolgus monkeys, both SPY002-091 and SPY002-072 exhibit a pharmacokinetic half-life of approximately 25 days compared to an observed half-life of 9-12 days for RG6631 and MK-7240. Structural studies employing cryo-EM show that each SPY002 mAb targets an epitope within a single TL1A subunit enabling binding to both monomeric and trimeric TL1A. Based on allometric scaling of SPY002-091 and SPY002-072 clearance in

NHPs, predictive simulations of their human PK properties suggest that Q8W-Q12W SC dosing will achieve therapeutic exposures in patients across a wide range of body weights and albumin concentrations.

Conclusion: We have characterized two anti-TL1A antibodies that exhibit high selectivity and affinity for TL1A, demonstrate effective blockade of the TL1A interaction with DR3, and potentially inhibit downstream cellular signaling. With an extended half-life observed in NHP, both SPY002-091 and SPY002-072 demonstrate therapeutic potential for effective and safe treatment of CD and UC with the advantage of infrequent SC dosing. Further preclinical and clinical studies are warranted to demonstrate this potential.

AQ312, A POTENT SMALL MOLECULE ARYL HYDROCARBON AGONIST, DEMONSTRATES EFFICACY IN EXPERIMENTAL MODELS OF INFLAMMATORY BOWEL DISEASE

W. Russell¹, M. Johansson¹, M. Hultqvist¹, J. Lund¹

¹Aqilion AB, Helsingborg, Sweden

Contact E-Mail Address: wayne.russell@aqilion.com

Introduction: Despite approval of several therapeutic approaches for the treatment of IBD, current treatments do not extend clinical response beyond the 40% 'therapeutic ceiling' and many patients do not achieve clinical remission.

The aryl hydrocarbon receptor (AhR) is a cytosolic ligand-dependent transcription factor that is expressed in many cell types. Activation of the receptor regulates many pathophysiological functions, including immune homeostasis and barrier integrity. AQ312 is a potent and selective AhR agonist undergoing preclinical development for the treatment of IBD.

Aims & Methods: The aim of the work was to determine the potency of AQ312 and evaluate the effects of AQ312 in preclinical animal models of IBD.

Cellular potency of AQ312 was determined using the human, mouse and rat AhR/ARNT reporter gene assay and compared to reference AhR agonists (Indigo Biosciences). The pharmacokinetics of AQ312 were measured in rats after acute administration (P.O.). Acute colitis was induced in C57Bl/6 mice by administration of DSS in the drinking water. Chronic colitis was induced in SCID mice by transfer of CD4⁺ T cells obtained from spleens of Balb/c mice. AQ312 was administered perorally (P.O.) at 1mg/kg, daily (d-7 to d9 in DSS and d0-d48 T cell transfer). Body weight was monitored throughout the study whilst colon weight and length, and inflammatory cells (flow cytometry) and cytokines (Luminex) in the colon were determined at necropsy. In addition, expression of cytochrome P450 1A1 (CYP1A1) was determined in colon tissue by RT-PCR to demonstrate AhR activation.

Results: AQ312 was a selective and potent activator of AhR, with similar potency for human, mouse and rat receptors (EC50 of 4.3, 2.1 and 3.9nM respectively). In rats, a single dose of AQ312 was rapidly cleared (T_{0.5}=1h) with little systemic exposure after 4h. Induction of acute or chronic experimental colitis in mice led to marked colon edema, immune cell infiltration and increased production of inflammatory cytokines. These effects were significantly reduced after per oral treatment with AQ312.

Conclusion: AQ312 is a potent and selective small molecule AhR agonist that is rapidly cleared in rodents. The molecule has demonstrated therapeutic benefit in 2 models of experimental colitis. AQ312 has the potential to be the 'best in class' AhR agonist for the treatment of IBD.

Introduction: SARS-CoV-2 exhibits an extra-pulmonary tropism, with up to 70% of COVID-19 patients experiencing at least one gastrointestinal (GI) symptom. Persistent viral presence has been observed in intestinal biopsies months after the virus has been cleared from the respiratory tract, which has been implicated in the development of long COVID symptoms. Despite these observations, the dynamics of SARS-CoV-2 infection within the intestine, as well as its potential to act as a viral reservoir and source of ongoing pathogenesis, remain largely unknown.

Aims & Methods: We recently established a robust mouse model to study the dynamics of intestinal SARS-CoV-2 infection by exposing the distal ileum of mice through ventral laparotomy and administering the virus directly into the lumen.

Results: In wild-type (WT) C57Bl/6 mice, after perfusion, viral RNA was detected throughout the GI tract at 7 days post infection (dpi), not only at the site of initial infection, but also in other regions such as the esophagus, stomach, duodenum, jejunum, colon, and rectum. Moreover, viral RNA was also found in extra-intestinal sites, including the salivary gland, liver, and brain. In *Stat1*^{-/-} mice with impaired type I, II, and III interferon signaling, the levels of viral RNA as well as nucleocapsid antigens in the GI tract were 10 to 100 times higher than those in WT mice. Virus also successfully disseminated to systemic organs such as the heart, lung, kidney, brain, and spleen. Viral shedding in feces was observed from 3 to 7 dpi in *Stat1*^{-/-} mice but not WT mice. Notably, rapid secretory diarrhea was observed in these mice, marking the first instance of diarrhea induced by SARS-CoV-2 infection in a mouse model. Additional studies are ongoing to further characterize these findings, including the assessment of the timing of viral replication, titration of infectious viruses, detailed histological analysis, and immunological profiling.

Conclusion: These results emphasize the usefulness of this mouse model in exploring the mechanisms underlying the impact of SARS-CoV-2 on the intestines locally and systemically. The study also underscores the critical role of interferon signaling in restricting intra-intestinal replication and preventing the virus from spreading to other organs. This has important clinical implications, particularly for individuals taking JAK inhibitor medications, which could affect the interferon response and potentially increase susceptibility to more severe outcomes from SARS-CoV-2 infection.

Introduction: The intestinal epithelium is the most regenerative tissue in the human body and an essential interface between the microbial ecosystem and the underlying mucosa, orchestrating both immune-mediated and metabolic functions. Mitochondrial signaling and metabolism controls the phenotype and function of intestinal epithelial cells (IECs) and mitochondrial perturbation is associated with chronic inflammation. We hypothesize that disruption of microbial-metabolic circuits and impaired metabolic flexibility of IECs contribute to the initiation and progression of tissue injury underlying chronic inflammation.

Aims & Methods: To address the role of mitochondrial impairment in epithelial homeostasis, conditional deletion of Heat shock protein 60 (Hsp60) was induced in the epithelium of Hsp60^{ΔAIEC} and Hsp60^{ΔAIEC};*Il10*^{-/-} mice under specific pathogen free and germfree conditions. Blinded histological analysis was used to assess metabolic injury and tissue inflammation. Additional 16S rRNA and shallow shotgun sequencing as well as metaproteomic analysis were performed to identify microbiome changes at the compositional and functional levels. Nanostring analysis and single-cell RNA sequencing (scRNA-seq) were used to identify epithelial cell population-specific transcriptional responses and to validate these gene signatures in resected tissues from Crohn's disease patients.

Results: Hsp60 deletion in IECs leads to the disruption of mitochondrial metabolism and the development of irregular crypt architecture, referred to as metabolic injury. Tissue lesions and IBD-related colitis are accelerated in Hsp60^{ΔAIEC};*Il10*^{-/-} mice. Germfree mice are protected from injury and inflammation, demonstrating a causal contribution of bacteria to metabolic injury. Mitochondrial perturbation in Hsp60^{ΔAIEC} mice is associated with microbial dysbiosis, including an increased abundance of *Bacteroi-*

des spp., which are maintained during sustained inflammation in Hsp60^{ΔIEC}/110^{-/-} mice. Consistently, *B. caecimuris* triggers tissue aberration in monocolonized-Hsp60^{ΔIEC} mice, supporting its deleterious role in tissue homeostasis. Furthermore, metaproteomic analysis revealed a metabolic adaptation of *B. caecimuris* in response to tissue injury. Importantly, the clinical relevance of *Bacteroides spp.* is confirmed in a combined analysis of three IBD cohorts (N=560 patients). Transcriptional profiling of the epithelium identified a gene signature in injury-associated sub-populations, including *Ido1*, *Nos2* and *Duox2*. Remarkably, the identified metabolic injury gene signature discriminates inflamed (N=196) versus non-inflamed (N=147) mucosa in CD patients, thus validating the human relevance of epithelial mitochondrial disruption in IBD.

Conclusion: Bacterial presence is a key driver of intestinal injury and metabolic injury associates with dysbiotic changes, notably expansion of *Bacteroides spp.* and their metabolic adaptation. Furthermore, mitochondrial perturbation induces a metabolic injury signature, which differentiates inflamed versus non-inflamed mucosa in IBD patients, strengthening the hypothesis of unresolved metabolic injury as a novel concept in the pathogenesis of intestinal inflammation.

LYNCH SYNDROME AND THYROID NODULES: A SINGLE CENTER EXPERIENCE

I. Spinelli¹, S. Moffa¹, F. Fianchi¹, T. Mezza¹, F. Cinti¹, G. Di Giuseppe¹, C. Marmo¹, G. Ianaro¹, F.R. Ponziani¹, A. Tortora², M.E. Riccioni¹, A. Giaccari¹, A. Gasbarrini¹

¹Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy,

²Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy

Contact E-Mail Address: irenespinelli1@gmail.com

Introduction: Lynch syndrome (LS) is an autosomal dominant genetic disease associated with germ-line mutations of genes involved in mismatch repair (MLH1, MSH2, MSH6 and PMS2) and the EPCAM gene. LS patients are at increased risk for colorectal cancer and other malignancies (especially endometrial, ovarian, and gastric cancer). There are few reported cases of thyroid cancer in patients suffering from LS.

Aims & Methods: To systematically investigate the presence of thyroid nodules in LS patients, to assess their cytologic classes and to explore its association with genetic features of the disease. A retrospective and descriptive analysis was conducted to include all LS patients followed at CEMAD (Centro Malattie Apparato Digerente) of Fondazione Policlinico Universitario A. Gemelli IRCCS. For each patient, characteristics of LS disease and previous history of thyroid disease were evaluated. Majority of patients underwent thyroid ultrasound (US) and nodule cytology was performed when needed. Gene mutations were reviewed for each patient with thyroid nodules and previous history of thyroid disease.

Results: A total of 139 LS patients, 52 males and 87 females, were included in the study. 103 patients (74%) underwent thyroid ultrasound examination, and 7 patients (5%) had a previous history of thyroid disease (cancer or multinodular goitre). For these two groups, mean age was 51.9 years. 29 patients (21%) did not already perform US at the time of analysis. Thyroid nodules were found in 62 patients (60%) who underwent US and 9 of them (14%) had suspicious features of malignancy inducing fine-needle aspiration biopsy. Cytologic analysis classified 7 of 9 cases (78%) as TIR2 and 2 (22%) as TIR3a. Between patients with nodular thyroid disease (single nodule, multinodular goitre and cancer), most of them (25 patients, 36% of total) were carriers of MSH6 mutation, while 22 (32%), 17 (24%) and 5 (7%) had MSH2, MLH1 and PMS2 mutations, respectively.

Conclusion: A high prevalence of thyroid nodules is found in patients with Lynch Syndrome, especially in MSH6 carrier patients. Performing at least one thyroid ultrasound examination is suggested for detection of nodular thyroid disease in LS patients. Systematic investigations are needed to estimate their prevalence, features, and risk of malignant transformation.

Introduction: Colorectal cancer (CRC) is one of the most common malignancies worldwide. Oxysterol binding protein 3 (OSBPL3) is a protein involved in lipid binding and transport and is known to play an essential role in tumorigenesis. However, its expression and function in colorectal cancer (CRC) is unclear.

Aims & Methods: This study included patients who underwent CRC surgery at Gachon University Gil Medical Center between April 2010 and January 2013. We analyzed 448 patients with primary colorectal cancer (CRC) who underwent surgery and had preserved paraffin blocks. Using immunohistochemical staining, a clinically applicable, rapid, and highly accurate assay method, we aimed to detect OSBPL3 expression in CRC and correlate it with clinicopathologic characteristics, prognosis, and survival to identify novel patient-specific biomarkers.

Results: The 5-year event-free survival (EFS) and disease-specific survival (DSS) hazard ratios (HRs) of the OSBPL3^{High} subgroup were 1.65 (95% confidence interval (CI): 0.99-2.76, $p = 0.05$) and 1.49 (95% CI: 0.89-2.61, $p = 0.20$), respectively. When tumor node metastasis (TNM) staging and OSBPL3 expression were combined, the 5-year EFS and DSS HRs of patients with CRC with OSBPL3^{High} expression cancer at the same TNM stage (stage III/IV) were 4.06 (95% CI: 2.72-6.07, $p = 0.001$) and 4.41 (95% CI: 2.91-6.68, $p = 0.001$), respectively, compared to those with OSBPL3^{Low} expression cancer, indicating a poor prognosis. Therefore, OSBPL3^{High} expression is associated with poor prognosis and survival rate in CRC patients. Combining OSBPL3 expression with TNM staging can predict CRC prognosis and survival rate more accurately.

Conclusion: Our data show that increased expression of OSBPL3 is associated with poor prognosis and survival rate in CRC patients. By combining OSBPL3 expression with TNM staging, we can more accurately predict the prognosis of CRC.

Disclosure: Nothing to disclose.

ANTI-TUMOR EFFECT OF WEE1 INHIBITOR AZD1775 ON COLORECTAL CANCER

M. Ariyoshi¹, H. Takigawa¹, Y. Kitadai¹, D. Shimizu¹, R. Miyamoto¹, Y. Hiyama¹, Y. Urabe¹, S. Oka¹

¹Hiroshima University Hospital, Department of Gastroenterology, Hiroshima, Japan

Contact E-Mail Address: misa4235@hiroshima-u.ac.jp

Introduction: Wee1 negatively regulates the G2/M checkpoint of the cell cycle, inhibiting cells with DNA damage from entering mitosis and inducing apoptosis. Although efficacy of Wee1 inhibitors as single agents or in combination with other agents has been reported in a variety of carcinomas and the association between Wee1 inhibitors and tumor immunity

has been reported, the effect of Wee1 inhibitors on the tumor immune microenvironment in colorectal cancer (CRC) has not been clarified. Since *p53* and *KRAS* are involved in cell cycle regulation at the G1/S checkpoint, mutations in them may increase dependence on the G2/M checkpoint for DNA repair, making Wee1 inhibitors more effective.

Aims & Methods: This study aimed to clarify the association between Wee1 expression and clinicopathological features in CRC and the effect of Wee1 inhibitors on the tumor immune microenvironment in CRC. Study 1: We performed immunostaining on 152 CRC cases surgically resected at our hospital between May 2013 and February 2015, and classified them into positive and negative groups according to the degree of Wee1 expression and investigated the association between Wee1 expression and clinicopathological features. Study 2: We measured Wee1 expression levels by Realtime PCR on 10 human-derived CRC cell lines and 2 mouse-derived CRC cell lines. We examined the effect of Wee1 inhibitor (AZD1775) on cell proliferation using Timelapse system. We examined the effect of Wee1 inhibitor on cell cycle using Cell Cycle Analysis Kit. We examined the effects of Wee1 inhibitor on apoptosis induction were examined using the Apoptosis Detection Kit. Study 3: We created the CRC orthotopic transplantation mouse model by transplanting the CRC cell line MC38 derived from C57BL/6 mice into the cecum of mice, comparing the tumor sizes of the control and treatment groups treated with Wee1 inhibitor for 21 days, and evaluating the effect of Wee1 inhibitor on the tumor immune microenvironment by immunostaining and RNA sequencing of mice tumor specimens.

Results: Study 1: No significant association was found between Wee1 expression and clinicopathological features or prognosis. However, overall survival rate was significantly higher in Wee1 positive and *KRAS*-mutant patients compared to Wee1 negative and *KRAS* wild-type patients. Study 2: Real time PCR showed that Wee1 expression was higher in most CRC cell lines than in normal colon mucosa. Wee1 inhibitor attenuated cell proliferation in a concentration-dependent manner in all CRC cell lines, and the effect was independent on Wee1 expression level. Cell cycle analysis showed that the percentage of cells in G2/M phase increased after exposure to Wee1 inhibitor, especially in cell lines with both *p53* and *KRAS* mutations. In addition, the number of apoptotic cells increased after exposure to Wee1 inhibitor, but in the cell lines with *KRAS* mutation and *p53* wild type, the number of apoptotic cells did not increase. Study 3: In the orthotopic transplanted mouse model, tumor volume was significantly smaller in the treated group compared to the control group, and immunohistological examination and RNA sequencing of mice tumor specimens showed enhanced tumor immunity and suppressed stromal reaction.

Conclusion: Wee1 inhibitor attenuated CRC cell proliferation through modulating cell cycle, especially in cell lines with *p53* mutation and attenuated tumor growth via enhancement of tumor immune response and suppression of stromal reaction in orthotopic transplanted mouse model. Wee1 inhibitor AZD1775 could be the promising treatment option for CRC.

Introduction: In the endoscopic diagnosis of superficial nonampullary duodenal epithelial tumor (SNADET), it is not easy to differentiate carcinoma from adenoma. On the other hand, SNADETs can be classified into gastric and intestinal phenotypes of mucin phenotype, and it has been reported that carcinomas of the gastric phenotype in particular show a poor prognosis. If the mucin phenotype can be predicted only by endoscopic findings, it may be possible to estimate the biological malignancy of SNADETs. Then, the following studies were conducted, focusing on it as a new endoscopic diagnosis.

Aims & Methods: The aim of this study was to clarify the endoscopic findings of SNADET in each mucin phenotypes. Between August 2018 and April 2021, 500 cases of suspected SNADET in our hospital were prospectively entered for analysis. Finally, 401 cases with 401 lesions that were treated endoscopically and pathologically diagnosed as SNADET were included and analyzed. Two pathologists with expertise in gastrointestinal pathology performed histological diagnosis according to the Vienna Classification (VCL) and evaluation of mucin phenotypes based on the results of immunostaining for CD10, MUC2, MUC5AC, and MUC6. Each endoscopic finding was compared between gastric and intestinal phenotype, and multivariate analysis was performed using a logistic regression model.

Results: With regard to pathological evaluation, 289 (72.1%) cases were diagnosed as VCL category 3 and 112 (27.9%) cases were diagnosed as VCL category 4/5. The details of mucin phenotypes in this SNADETs were as follows: 44 pure gastric, 11 gastric predominant, 18 mixed gastrointestinal, 159 intestinal predominant, and 180 pure intestinal phenotypes, respectively, and the percentages of VCL category 4/5 were 63.6%, 54.5%, 38.9%, 30.8% and 16.1%, respectively ($P < 0.01$, Cochran-Armitage trend test). Compared in the two groups of gastric phenotype (pure gastric and gastric predominant) and intestinal phenotype (pure intestinal and intestinal predominant), there were significant differences in location (from the bulb to the proximal descending part (hereafter, proximal side): 82.2% vs 29.0%, $P < 0.01$), lesion diameter (20.0 mm vs 15.0 mm, $P < 0.05$), macroscopic type (Type 0-I: 60.0% vs 14.8%, $P < 0.01$), redness (present: 68.9% vs 32.8%, $P < 0.01$), surface structure (closed-loop structure (CLS): 84.4% vs 29.6%, $P < 0.01$), white opaque substance (WOS) (absent: 51.1% vs 11.0%, $P < 0.01$). In multivariate analysis, location (proximal side: OR 4.5, 95%CI 1.8-10.9), macroscopic type (Type 0-I: OR 2.5, 95%CI 1.1-5.7), surface structure (CLS: OR 5.4, 95%CI 2.1-13.8), WOS (absent: OR 2.9, 95%CI 1.3-6.7) were independently and significantly associated with being gastric phenotype of SNADET.

Conclusion: This study showed that SNADETs with gastric and intestinal phenotypes were found to show different endoscopic findings.

Disclosure: There is no conflict of interest in this study.

Introduction: Gastric cancer is one of the most common malignant tumors with high morbidity and mortality. Manifestations of early gastric cancer often lack specificity, leading to delayed diagnosis, with a majority of cases progressing to advanced stages upon identification. Additionally, traditional tumor markers such as CEA, CA19-9, and CA72-4 exhibit limited sensitivity and specificity. Hence, there exists an urgent imperative to discover novel predictive and diagnostic markers for early-stage gastric cancer. Unlike gastric mucosal tissue biopsy, which is restricted to localized sampling, gastric juice offers a more comprehensive and representative reflection of the overall gastric environment. However, the acidic nature of gastric juice and the presence of multiple digestive enzymes present challenges for the direct detection of protein markers in gastric juice. Exosomes, characterized by lipid bilayer membranes, serve to stabilize proteins and facilitate their transportation within the microenvironment and distant regions, thereby exerting regulatory functions and offering potential diagnostic significance.

Aims & Methods: In this study, we endeavored to identify protein markers within gastric juice exosomes of early gastric cancer patients with enhanced sensitivity and specificity. Briefly, gastric juice samples were collected from early gastric cancer patients and chronic gastritis patients matched for age and gender, who underwent gastroscopy at Peking University Third Hospital. Exosomes were isolated through ultracentrifugation. Following protein quality control, label-free quantitative proteomics was employed to investigate the differential protein composition between the two groups. Additionally, we conducted further analysis to explore the interaction among the differential proteins in the two groups with KEGG enrichment analysis. Moreover, immunohistochemical (IHC) staining, western blot and electron microscopy immunocolloid gold staining were conducted to validate the proteomic findings.

Results: The results of differential protein expression analysis indicated the presence of 21 up-regulated proteins and 32 down-regulated proteins in gastric juice exosomes of the early gastric cancer group compared to the gastritis group (fold change >2 , $P < 0.05$). Further KEGG pathway enrichment analysis revealed that the differentially expressed proteins were primarily enriched in pathways related to glucose and lipid metabolism, immunomodulation, and the PPAR signaling pathway. In comparison to the gastritis group, the levels of CD13 protein in gastric juice exosomes were significantly increased by 7.45-fold ($P = 0.043$) in early gastric cancer patients. IHC staining was conducted and the results demonstrated significantly higher expression levels of CD13 in gastric mucosa tissues of gastric cancer patients compared to those of patients with gastritis, consistent with those in gastric juice exosomes. Additionally, Western blot confirmed elevated levels of CD13 in gastric juice exosomes of the early gastric cancer group compared to the gastritis group, further corroborating the proteomics findings. Furthermore, electron microscopy immunocolloid gold staining revealed predominant expression of CD13 on the membrane of gastric juice exosomes, providing a crucial basis for its subsequent direct detection through antigen-antibody recognition.

Conclusion: In summary, our findings suggested that CD13 in gastric juice exosomes may serve as a promising marker for early gastric cancer screening, aiming to facilitate early diagnosis and treatment interventions.

Introduction: Esophageal squamous cell carcinoma (ESCC) is the most common histological type of esophageal cancer in eastern Asia and Africa. Diagnosis at early stage is crucial to reduce the mortality of ESCC. Currently, esophagogastroduodenoscopy (EGD) is the golden standard for screening ESCC, however, the patient compliance rate has been low due to the invasiveness and high cost of EGD. Thus, there is an unmet need for the development of diagnostic modality that enables non-invasive early detection of ESCC.

Aims & Methods: The purpose of this study is to construct a urinary exosomal miRNA panel as a least invasive test that can detect ESCC with high accuracy and validate its performance in a prospective cohort enriched with early ESCC. We prospectively collected urine samples from 161 ESCC patients and 180 healthy controls (HC) at five institutions from September 2019 to March 2023. Exosomes were extracted from urine specimens by polymer precipitation method, and exosomal miRNAs were subjected for comprehensive expression analysis by small RNA seq. Of the 341 total samples, 309 samples (90.6%) that passed the QC check were selected for subsequent data-analysis. In the training cohort (100 samples of ESCC and 98 samples of HC), we measured the expression of 328 miRNAs to identify candidate biomarker miRNAs. A miRNA diagnostic panel was constructed using machine learning analysis, and diagnostic performance was evaluated using a 5-fold cross-validation method. In the validation cohort (50 samples of ESCC and 61 samples of HC), the diagnostic performance of the urinary miRNA diagnostic panel was verified with blind to clinical information.

Results: In the RNAseq analysis of the training cohort (ESCC; mean age 68.2 years, 77.9% male; HC; mean age 58.1 years, 76.3% male), 33 out of 328 miRNAs were differentially expressed between ESCC and HC. Out of the 33 dysregulated miRNAs, 21 were upregulated and 12 were down-regulated. A multi-miRNA biomarker panel composed of miRNAs that were individually significant and non-significant between ESCC and HC had a diagnostic performance of AUC 0.89 (95% CI 0.84 to 0.94) by 5-fold cross-validation. In the validation cohort (ESCC; mean age 63.0 years, 78.0% male, median size 32mm, Stage I/II/III/IV 54/10/26/10%, HC; mean age 51.0 years, 52.5% male), The diagnostic performance of the miRNA diagnostic panel was AUC 0.85(95% CI 0.80 to 0.90), with a sensitivity of 84%, specificity of 73.8%, and accuracy of 78.4% at a pre-defined cutoff value. There was no confounding of diagnostic performance by age, gender, BMI, history of alcohol consumption or smoking. The sensitivity by clinical stage of ESCC was 88.9/80.0/77.8/80% for Stage I/II/III/IV.

Conclusion: We developed and validated a urinary exosomal miRNA diagnostic panel, which may be a new non-invasive diagnostic method that contributes to the early detection of ESCC.

CLINICOPATHOLOGICAL FEATURES AND CARCINOGENIC POTENTIAL OF SERRATED POLYPOSIS SYNDROME

R. Hirai¹, H. Kinugasa¹, M. Otsuka¹

¹Okayama University Hospital, Gastroenterology and Hepatology, Okayama, Japan

Contact E-Mail Address: ryosukehirai1122@gmail.com

Introduction: Serrated Polyposis Syndrome (SPS) is a disease characterized by multiple serrated lesions (SLs), such as sessile serrated lesions (SSL), traditional serrated adenomas (TSA), and hyperplastic polyps (HP). Although it has been suggested that SPS may be a high risk for developing colorectal cancer, it may have been frequently missed in the past due to low recognition and diagnostic complexity. Epidemiological investigations and studies on its pathogenesis are extremely limited, especially with the new WHO classification revised in 2019¹.

Aims & Methods: This study aimed to characterize the clinicopathological and molecular features of carcinogenesis in SPS. We retrospectively reviewed the findings of colonoscopy of 640 patients who underwent endoscopic/surgical resection of one or more serrated lesions at Okayama University Hospital between January 2012 and October 2023. Patients were classified into two groups: those matching the diagnosis of SPS (SPS group) and others (Sporadic SL group). The control group consisted of patients who underwent colonoscopy as a screening examination between January and December 2022 and had no serrated lesions. Patient background, incidence of colorectal cancer, and clinicopathological findings of all resected lesions including tubular adenoma (TA) were evaluated in the above three groups. Genomic DNA was extracted from FFPE tissues of all colorectal cancers, and mutation analysis of KRAS (codon 12 and 13) and BRAF (codon 600) were performed by direct sequencing of the PCR products. Microsatellite instability (MSI) analysis was performed by coelectrophoretic sequencing of five quasi-monomorphic mononucleotide markers (NR-21, NR-22, NR-24, BAT-25, and BAT-26).

Results: The subjects were 55 in the SPS group, 585 in the Sporadic SL group, and 368 in the control group. There were no significant differences in age, sex, or history of cancer in other organs. The incidence of colorectal cancer was 18 (32.7%) in the SPS group, 98 (16.8%) in the Sporadic SL group, and 20 (5.4%) in the control group, showing a significant difference among the three groups ($p < 0.001$). Details of 21 colorectal cancer lesions in 18 patients in the SPS group were as follows: left/right side, 15 lesions/6 lesions; early/advanced cancer, 16 lesions/5 lesions. Four of the six (67%) right-sided lesions were MSI-high and/or had BRAF mutations, suggesting carcinogenesis via the serrated neoplasia pathway. In contrast, 12 of the 15 (80%) lesions on the left side were histologically coexistent with adenoma components and/or had KRAS mutations, suggesting carcinogenesis via the adenoma-carcinoma pathway. In addition, of the 640 patients with SLs (SPS group and Sporadic SL group), 458 (71.6%) had concomitant TAs and the incidence of colorectal cancer was significantly higher in patients with TAs (96/458, 21.0%) than in those without TAs (20/182, 11.0%) ($p = 0.003$).

Conclusion: SPS has a high incidence of colorectal cancer, and the coexistence of SLs and TAs is suggested to be a risk factor for cancer development. Interestingly, carcinogenesis via the adenoma-carcinoma pathway from comorbid TAs, rather than the serrated-neoplasia pathway, is dominant in SPS.

Introduction: Colorectal cancer, with an estimated two million new cases each year worldwide, poses a significant socioeconomic burden on modern society. It is the second leading cause of cancer-related deaths, accounting for nearly one million premature deaths annually.

Aims & Methods: The role of Signal Transducer and Activator of Transcription 2 (STAT2) in this context is not yet understood, and no therapies targeting this transcription factor are currently being pursued. We explored the function of STAT2 in colorectal cancer by employing experimental mouse models, as well as conducting functional assays with three-dimensional tumoroids in the context of anticancer therapy.

Results: In vivo studies showed that Stat2KO mice were more resistant to developing tumors in both inflammation-driven and inflammation-independent models of experimental colorectal cancer. This unexpected outcome could not be reconciled with the known role of STAT2 in inducing cell death downstream of type I interferon signaling. We consequently performed ex vivo experiments with tumoroids derived from Stat2KO mice carrying the multiple intestinal neoplasia (Min) mutant allele of the adenomatous polyposis coli (Apc) gene. These tumoroids exhibited slower growth, were generally smaller in size, and showed a higher degree of differentiation compared to those derived from ApcMin/+ wildtype mice. Remarkably, when treated with anti-tumor agents that induce cell death through various mechanisms, tumoroids derived from ApcMin/+ Stat2KO mice were found to be highly sensitive. Additional functional studies indicated that the underlying mechanism might involve a STAT2-dependent disruption of innate immune DNA sensing.

Conclusion: Our results establish STAT2 as a promoter of colorectal cancer and a contributor to resistance against anti-tumor therapy. These findings suggest that targeting STAT2-dependent signaling could be a promising therapeutic strategy for patients with colorectal cancer.

Introduction: The detection of microsatellite instability (MSI) in tumor tissue is of high relevance for (1) identifying patients eligible for immune checkpoint blockade and (2) Lynch syndrome carriers. Gold standard for MSI analysis are DNA-based methods that are encompassing PCR-based amplification of short repetitive sequence stretches (microsatellites) and assessing length variations in the respective amplicons.

However, diagnostic complications can arise due to potential artifacts known as stutter bands, which are erroneous insertions or deletions occurring in PCR amplification that make it difficult to detect the true length of the microsatellite fragment. Correctly distinguishing these artifacts from true genetic insertion/deletion (indel) mutations in microsatellites *in vivo* is crucial for accurate MSI fragment length assessment. Factors such as PCR cycle number, laboratory conditions, and DNA quality can influence the occurrence of stutter bands. A thorough understanding of these factors is vital for preventing diagnostic errors. Moreover, improving our knowledge of changes during PCR amplification can advance our understanding of the evolution of these mutations in microsatellites *in vivo*.

Aims & Methods: Fluorescent multiplex PCR for the BAT25, BAT26, BAT40, and CAT25 microsatellite fragments was performed on multiple microsatellite stable and microsatellite unstable samples across different PCR cycle counts. Peak distribution was assessed for each reaction, and peak profiles were evaluated in relation to cycle numbers for different template DNA samples analyzed. In addition, we analyzed peak profiles to infer the potential fragment lengths prior to amplification, i.e. closest to the original sample.

Results: We analyzed the formation of stutter bands during PCR analysis in microsatellite fragments and were able to highlight a shift in the distributions of PCR peaks with increasing cycle count. Amplified fragment sizes tended to be of shorter length with higher numbers of cycles. This was paralleled by an increase of stutter bands in high compared to low cycle reactions. Additionally, *in silico* modeling of our peak data demonstrates how the length of microsatellite markers, the read depth and the number of PCR cycles affect the reliability and interpretability of MSI detection PCR.

Conclusion: Our results indicate that optimizing reaction conditions is a critical step to standardizing MSI detection by PCR. This may have important implications in MSI diagnostic procedures, particularly when assessing small samples with low DNA template concentration or tumors with borderline MSI status. Our observations suggest that a comprehensive understanding of the peak data produced in fluorescent multiplex PCR can significantly improve diagnostic capability in detecting MSI status in tumor samples and can further insight into the development of MSI mutations *in vivo*. Developing mathematical models that describe cycle-wise changes of peak distributions is the next step to improve the accuracy of PCR-based MSI testing.

Introduction:

Hepatocellular carcinoma (HCC) is the second leading cause of cancer-related deaths. Unresectable HCC can be treated with transarterial chemoembolization (TACE), which causes hypoxia and induces the expression of vascular endothelial growth factor (VEGF). Antiangiogenic drugs can be useful in this setting.

Aims & Methods: This study aims to compare TACE plus Apatinib (antiangiogenic drug, TACE+A) versus TACE plus Apatinib plus Camrelizumab (immune checkpoint inhibitor, TACE+AC). We performed a systematic review in PubMed, Embase, Cochrane and Web of Science databases, searching for studies comparing TACE+A versus TACE+AC in patients with unresectable HCC. The primary outcomes were overall survival and disease-free progression survival. The secondary outcomes were treatment response and adverse events grade III or IV. The odds ratio (OR) was used for binary outcomes with their respective 95% confidence interval (CI). Heterogeneity was assessed using the Cochran Q test and I^2 statistics.

Results: The meta-analyses included 3 studies and 1,134 patients. There was a significant difference favoring TACE+AC in overall survival (HR 0.41; 95% CI 0.28 to 0.60; $p < 0.01$; $I^2 = 87\%$) and in disease-free progression survival (HR 0.29; 95% CI 0.15 to 0.55; $p < 0.01$; $I^2 = 0\%$) compared to TACE+A. There is no difference in adverse events grade III or IV between groups (OR 1.08; 95% CI 0.83 to 1.40; $p = 0.586$; $I^2 = 0\%$).

Conclusion: In patients with unresectable HCC, TACE+AC demonstrated superior efficacy compared to TACE+A. The two combinations showed similar safety profiles.

Introduction: The gut microbiota is often altered in chronic liver diseases and hepatocellular carcinoma (HCC), and increasing evidence suggests that it may influence response to cancer immunotherapy. Strategies to modulate the gut microbiome (i.e., fecal microbiota transplant (FMT)) may help to improve efficacy of immune checkpoint inhibitors (ICIs) or even overcome resistance to ICIs.

Aims & Methods: In this single-center phase II pilot study (ClinicalTrials.gov ID: NCT05750030), we plan to include 12 patients with advanced HCC who progressed on atezolizumab/bevacizumab. Patients will receive atezolizumab/bevacizumab every 3 weeks in combination with a single FMT via colonoscopy from donors with HCC who responded to PD-(L)1-based immunotherapy. The primary endpoint is safety, measured by incidence and severity of treatment-related adverse events (TRAEs). The main secondary endpoint is best overall response (BOR) according to RECISTv1.1 and mRECIST. Here, we report results of a preplanned interim analysis.

Results: Of 6 patients included so far, 5 were male, 5 had BCLC stage C, and 5 had Child-Pugh class A. All patients underwent successful FMT without any periinterventional complications. TRAEs related to FMT were all low-grade (grade 1-2) and included bloating (n=2), constipation (n=2), and diarrhea (n=1). TRAEs related to atezolizumab included one grade 2 pruritus, and TRAEs related to bevacizumab included arterial hypertension (one grade 3 and two grade 2) and proteinuria (one grade 3 and one grade 1). All patients had at least one follow-up imaging. Two patients had partial response, 3 patients had stable disease, and 1 patient had progressive disease as BOR according to both RECISTv1.1 and mRECIST, which corresponds to an objective response rate of 33% and a disease control rate of 83%.

Conclusion: Based on acceptable safety and promising efficacy results, the decision to continue recruitment in this trial was made. An update with longer follow-up will be presented at the meeting, including analyses of the gut microbiome.

Introduction: Alpha fetoprotein (AFP) and prothrombin induced by vitamin K absence/antagonist II (PIVKA-II) are biomarkers for hepatocellular carcinoma (HCC), which have been extensively in the diagnosis of HCC, while their use in the prognosis prediction remains poorly assessed. Recently, a new algorithm (ASAP) - including age, gender, AFP and PIVKA-II - has been validated as an alternative to GALAD for prediction of HCC development with a cut-off of 0.52. The identification of predictors of HCC recurrence after curative treatment has always been relevant to patients' management, and now may have further utility with the arrival of adjuvant therapies.

Aims & Methods: The aim of our study was to evaluate the predictive role of AFP and PIVKA-II alone or combined in the ASAP score for HCC recurrence in patients who achieved a complete response (CR) after locoregional treatment. In this single-center, observational ongoing study, we have enrolled 156 consecutive patients with first diagnosis of HCC treated by ablation (MWTa) or chemoembolization (TACE). CR was evaluated by CT-scan 1 month after treatment, afterwards patients were evaluated every three months by CT-scan, clinical and biochemical features until recurrence, death or last follow up. PIVKA-II and AFP levels were measured at the day of treatment by Fujirebio assays, Japan.

Results: 81 (52%) patients with HCC who achieved CR after the first treatment were included: median age 66 (40-87); 83% men, 57% HCV-positive, 91% Child-Pugh A, 85% BCLC 0/A, 53% MWTa. The day of treatment, the

median AFP was 6.3 ng/mL (1.3-3,537), median PIVKA-II was 112 (16-5,090) mAU/mL, median ASAP score was 0.405 (-3.44-6.64; 47% with ASAP value > 0.52). During follow up, HCC recurred in 47 (58%) patients [median time to recurrence was 298 (41-1256) days after achieving CR]. PIVKA-II [HR 2.53 (95%CI 1.47-4.35), p<0.001] and age [HR 1.03 (95%CI 1.00-1.07), p=0.013] were the only independent predictors of overall HCC recurrence by a multivariable model for single variables only, while the ASAP score [HR 1.31 (95%CI 1.12-1.52), p<0.001] was the only independent predictor of recurrence in a multivariable model including only scores and algorithms. PIVKA-II [HR 2.14 (95%CI 1.09-4.18), p=0.026] was the only independent predictor of early recurrence in the first multivariable model, while platelet to lymphocyte ratio [PLR; HR 1.02 (95%CI 1.00-1.04)] and ASAP score [HR 1.30 (95%CI 1.03-1.64)] were independent predictors of early recurrence according to the second model. Adopting the ASAP cut-off of 0.52, the algorithm independently predicted HCC recurrence [HR 3.54 (95%CI 1.86-9.75), p<0.001], but did not predict HCC early recurrence [HR 1.95 (95%CI 0.87-4.34), p=0.103].

Conclusion: The ASAP algorithm may accurately predict HCC recurrence and early recurrence after complete radiological response, deserving further studies to refine the model.

Introduction: Although atezolizumab plus bevacizumab treatment (AB) has been developed as the first immune therapy for unresectable hepatocellular carcinoma (u-HCC) based on the results of the IMbrave 150 trial, there have been few reports of the therapeutic efficacy and safety of AB for u-HCC in real-world clinical practice with a large cohort.

Aims & Methods: This study aimed to elucidate the therapeutic outcome of AB. From 2020 to 2023, 1016 Japanese patients with u-HCC treated with AB in our hospitals were enrolled (median age: 74 years, initial line use:

697, BCLC stage 0 or A:B:C:D=77:408:512:19). Child-Pugh classification and modified albumin-bilirubin (ALBI) grade, in which the middle grade was divided into 2 sub-grades by an ALBI score of -2.27, were used for the assessment of hepatic reserve function. The therapeutic efficacy and safety of AB were evaluated, retrospectively.

Results: The median observation period was 12.5 months (IQR 6.8-21.2). Child-Pugh class A included 920 patients, B included 95, and C included 1, while ALBI grade 1 comprised 360 patients, grade 2 comprised 641 (grade 2a:2b=266:375), and grade 3 comprised 15. The median progression-free survival (mPFS) and overall survival (mOS) in the entire cohort were 7.6 months (95% CI 6.7-8.3) and 22.3 months (95% CI: 19.2-25.5). The mPFS/mOS according to Child-Pugh class (A:B:C) were 7.8/24.5, 5.0/9.4, and 0.4/1.1 months, respectively, while those according to modified ALBI (1:2a:2b:3) were 10.6/31.0, 8.0/22.1, 5.9/14.1, and 5.3/10.5 months, respectively (each $P<0.001$). According to BCLC stage (0 or A:B:C:D), mPFS/mOS were 14.5/not reached, 9.1/25.1, 6.0/19.1, and 2.4/10.5 months, respectively (each $P<0.001$). When PFS and OS were compared between initial and later line use groups, significant differences were observed (mPFS/mOS=7.9/24.9 vs. 6.5/18.8 months, respectively, each $P<0.05$). Adverse events (any grade>10%/grade 3 or more, %) included urine protein (31.7/9.3), fatigue (23.4/2.7), appetite loss (20.2/2.8), hypertension (18.1/5.5), hepatic function abnormality (17.0/5.1), ascites/edema (13.0/3.4), fever (12.4/1.0), and rash (11.5/1.4), with AE grade 5 observed in 9 patients (0.9%) (liver injury 4, interstitial pneumonia 3, esophageal varices bleeding 1, and colitis 1). Immune-related AE, which required steroids, was occurred in 148 (15.4%).

Conclusion: In the clinical practice of Japanese u-HCC patients numbering over 1000, AB showed favorable therapeutic results and similar safety to those of the IMbrave150 trial (median observation period 8.6 months). The prognostic improvement effect of initial line use might be better than that of subsequent lines. To obtain a better prognosis, the introduction of AB is recommended in patients with better hepatic reserve function, if possible.

Disclosure: Nothing to disclose.

Introduction: Hepatocellular carcinoma (HCC) is the most common form of primary liver cancer, predominantly diagnosed in patients with chronic liver diseases. The absence of specific biomarkers and the typically asymptomatic progression of the disease lead to delayed diagnosis. Patients with liver disease, including HCC, exhibit alterations in the gut

microbiome and increased bacterial permeability, factors that may influence disease progression and patient outcomes. In recent years, there has been a growing interest in exploring circulating microbiome signatures as potential indicators of liver disease status, providing a new avenue for understanding HCC.

Aims & Methods: Aims: To identify the signatures of the circulating blood microbiome associated with hepatocellular carcinoma, response to treatment and disease prognosis.

Methods: This study conducted a post-hoc analysis of the SORAMIC clinical trial utilizing peripheral blood plasma samples. For this analysis, blood plasma samples from a cohort of 71 patients with HCC were examined (25 treated with Sorafenib and 46 with SIRT/Sorafenib). Peripheral blood samples were collected at two time points: baseline (prior to the initiation of anti-tumor therapy) with all 71 patients included, and post-therapy (7 to 9 weeks after treatment) with 39 patients included. Additionally, peripheral blood samples were obtained from 52 control subjects, who were endoscopically diagnosed with colonic diverticulosis, to compare against the patient group. The composition of the circulating blood microbiome was assessed through 16S rRNA gene sequencing, targeting the V1-V2 hypervariable regions. Subsequent analyses focused on identifying associations with potential novel biomarkers for diagnosis, prognosis, and response to treatment.

Results: Patients with HCC had significantly diminished α -diversity of the circulating blood microbiome as compared to controls. Significant differences were also observed in between microbial communities of these two cohorts based on Bray-Curtis dissimilarity index. Patients with HCC had significantly higher levels of *Proteobacteria* and *Bacteroidetes* and lower levels of *Firmicutes* and *Campylobacterota*. Differential abundance analysis revealed that families of *Gordoniaceae*, *Cryomorphaceae*, *Burkholderiaceae*, *Comamonadaceae*, *Enterobacteriaceae* were significantly enriched in patients with HCC. At the genus level, patients with HCC had higher levels of *Gordonia*, *Fluviicola*, *Burkholderia*, *Limnohabitans* and *Escherichia/Shigella* and lower levels of *Corynebacterium*. HCC patients, who responded to treatment with SIRT/Sorafenib showed an increase in blood bacterial diversity, enrichment of families *Burkholderiales incertae sedis*, *Arcobacteraceae*, *Peptostreptococcaceae*, *Moraxellaceae*, genera *Sphaerotilus*, *Aliacrobacter*, *Rhodoluna*, *Giesbergeria*, *Microbacterium*, *Romboutsia*, *Arcicella*, *Pseudorhodofera* and depletion in families *Gordoniaceae*, *Cryomorphaceae* and genera *Cloacibacterium*, *Gordonia*, *Limnohabitans*, *Fluviicola* after the treatment. Levels of *Acinetobacter*, *Enhydrobacter* and *Micrococcus* in the blood before the HCC treatment were associated with patient prognosis.

Conclusion: Patients with HCC exhibit a unique circulating blood microbiome profile characterized by reduced bacterial diversity. Response to treatment is linked to an increase in α -diversity and changes in the circulating microbiome profile. Specific members of the circulating microbiome show potential prognostic capabilities, suggesting their utility as biomarkers for predicting disease progression and treatment outcomes in HCC.

Disclosure: Nothing to disclose.

Introduction: In 2022 the BCLC staging and treatment algorithm for hepatocellular carcinoma (HCC) management has been updated (BCLC_2022), granting for higher flexibility and customized management for HCC patients as compared to the 2018 version.

Aims & Methods: Aim of the study was to evaluate the feasibility of BCLC_2022 in daily clinical practice (BCLC_2018 as benchmark), its impact on response to treatment and on overall survival (OS).

We retrospectively evaluated data of 798 prospectively followed (year 2006 to 2022) patients with de novo HCC: 187 0, 371 A, 132 B, 87 C and 21 D, according to BCLC. First line treatment allocations were discussed by a multidisciplinary team (MTD), following updated recommendations. All patients were followed until death or end of follow-up (12/2022).

Results: Overall, the feasibility if BCLC increased from 51% for the BCLC_2018 to 69% for the BCLC_2022 ($p<0.001$): 56% to 73% stage 0 ($p=0.001$), 45% to 72% stage A ($p<0.001$), 51% to 65% stage B ($p=0.02$), while no changes were registered for stage C and D. Among BCLC 0 /A patients, 130 (23%) were treated with TACE, which is a "lower priority option" for these stages according to BCLC_2022. The rate of "downward stage migration" was significantly lower with BCLC_2022 (33% to 16%, $p<0.001$). "Downward stage migration" without curative intent was associated with a lower proportion of complete response to first line treatment in the early stages (0% vs 77%, $p=0.003$ in BCLC0; 0% vs 57%, $p=0.001$ in BCLC A) and to a shorter OS [6 months (IQR 2-16) vs 82 months (IQR 42-132), $p<0.001$ in BCLC 0] as compared to BCLC_2022. Similarly in early stages patients treated with a "lower priority option" had a lower proportion of complete response (82% vs 60%, $p=0.01$ in BCLC 0 and 74% vs 20%, $p<0.001$ in BCLC A) and a shorter OS [33 (IQR 23-61) vs 74 months (IQR 42-137) $p<0.001$ in BCLC A] as compared to those undergoing first choice treatments. In BCLC B and C, an upward stage migration was associated to a higher achievement of complete response (17% vs 52%, $p<0.001$ in BCLC B and 2% vs 41% $p<0.001$ in BCLC C), and granted a longer OS [(63 months (IQR 36-72) vs 28 (IQR 18-44), $p=0.003$ in BCLC B and 21 months (IQR 15-44) vs 11 months (IQR 4-25) in BCLC C] as compared to BCLC 2022. In BCLC 0 and undergoing a "downward stage migration" without curative intent was an independent predictor of mortality [HR 6.94 (95% CI 2.27-21.20) $p=0.001$], alongside with age [HR 1.08 (95% CI 1.06-1.13), $p<0.001$] and ALBI grade 3 [HR 9.34 (95% CI 1.21-72.19), $p=0.03$. Conversely, "upward stage migration" was independently associated to a lower mortality risk both in BCLC B" [HR 0.46 (95% CI 0.27-0.80), $p=0.006$] and C [HR 0.50 (95% CI 0.27-0.92) $p=0.03$].

Conclusion: The BCLC_2022 updated version of HCC staging and treatment system allowed a greater adherence to the algorithm in clinical practice, without adversely affecting the survival of patients. Choosing a "cu-

orative option" for early HCC granted longer survival, as well as the access to treatments with curative intent permits a survival benefit in selected patients in more advanced stages.

EFFICACY OF POSTOPERATIVE ADJUVANT THERAPIES IN PATIENTS WITH RESECTED CHOLANGIOCARCINOMA

H. Shin¹, Y.-K. Jung¹

¹Korea University Ansan Hospital, Dept. of Internal Medicine, Gyeonggi, South Korea

Contact E-Mail Address: shg0715@nate.com

Introduction: Surgical resection is an only curative treatment in cholangiocarcinoma (CCC). However, despite curative resection, recurrences are frequent so that most of the patients undergo bad prognosis. Adjuvant therapy in surgically resected CCC has not proved its clinical benefit until now.

Aims & Methods: This study aimed to evaluate the benefit of adjuvant therapy on overall survival (OS) and disease free survival (DFS). We categorized a retrospective cohort of 159 patients who underwent surgical resection for CCC into two groups based on their chosen treatment approach: observation group ($n=66$) and adjuvant chemotherapy/chemoradiation group ($n=93$). OS and DFS were estimated using the Kaplan-Meier method.

Results: There were no significant differences in age, gender, tumor differentiation, resection margin status (R0, R1), lymphovascular invasion, perineural invasion, lymph node metastasis, TNM stage between two groups. Adjuvant treatment did not show a significant improvement in overall survival (OS) with a median OS of 59 months in the observation group and 41 months in the adjuvant treatment group ($p=0.35$). However, in subgroup analyses based on the presence of lymph node involvement and the status of resection margin, adjuvant treatment was found to statistically significantly improve OS in the subgroups with LN+ group and R1 group, respectively. Tumor recurrence rate was 56% in observation group, 53% in adjuvant treatment group. The median DFS in each groups were 44 and 37 months ($p=0.08$). Adjuvant treatment didn't significantly extend DFS in LN+ subgroup, but showed improvement of DFS in R1 group.

Conclusion: Our study suggested potential benefit of adjuvant therapy in the aspects of OS in the selective group with LN+ and R1 among patients with resected CCC. However, a positive impact was noted in DFS only for the R1 group. A further randomized well controlled prospective study is warranted.

SURVIVAL ANALYSIS OF ALPHA-FETO PROTEIN NEGATIVE METASTATIC HEPATOCELLULAR CARCINOMA: A POPULATION-BASED STUDY

M. Mortagy¹, T. Kaung¹, M. Liaqat¹, A. ElGehiny², A. Abdelhameed³, K. Elguzouli¹, D. Sheppard¹

¹Hampshire Hospitals NHS Foundation Trust, Gastroenterology Department, Winchester, United Kingdom, ²MD Anderson Cancer center, Houston, United States of America, ³Alexandria University Faculty of Medicine, Alexandria, Egypt

Contact E-Mail Address: muhammad.liaqat@hhft.nhs.uk

Introduction: Hepatocellular carcinoma (HCC) is the sixth most common cancer in incidence and the third in mortality worldwide. Its incidence is variable worldwide. Seventy-two percent of cases occur in Asia. It is more common in males. Alpha-Feto protein is negative in only 30% of patients with HCC. 60-months survival of HCC ranges from 70% (for early stages) to 20% (for advanced stages). The overall median survival of metastatic HCC is 11 months. Patients with negative AFP usually have better survival than those with positive AFP. The effect of AFP negativity on metastatic HCC survival duration and the factors affecting survival of this subgroup of patients is not well studied.

Aims & Methods: This study aims to identify the factors affecting the overall survival of patients with AFP negative metastatic HCC and their survival duration. A total of 1146 patients with AFP-negative metastatic HCC diagnosed between 1975 to 2020 were extracted from the U.S. Surveillance, Epidemiology and End-results (SEER) program databases. Univariable and Multivariable Cox regression were performed, associated hazards ratio (HR) and Kaplan Meier curves/statistics were generated for overall survival analysis.

Results: Most patients were males (78.8%). Their mean age was 65.6. Most patients were of white race (74.9%) and of non-Spanish-Hispanic-Latino origin (79.8%). Most patients lived in metropolitan areas (87.6%) and earned \$75,000+ (37.3%). Most patients were married (48.1%). The mean tumor size was 9.93 cm with 75.1% > 2cm in size. Most patients had T0/T1 stage (41.1%) followed by T3 (32.7%). Most patients had N0/Nx stage (72.7%). Most patients didn't receive chemotherapy (62.1%).

The median survival of the cohort was 5 months (95% confidence interval: 5-6 months). The survival of the cohort was 99%, 28.3%, 8.5%, 3.8% at 1,12, 36 and 60 months respectively. Univariable Cox regression was statistically significant for age (HR 1.01), grade III (HR 1.55), grade IV (2.75), receiving chemotherapy (HR 0.48), black race (HR 0.80). Univariable Cox regression was non-statistically significant for sex, T stage, N stage, origin, rurality, marital status. Grade wasn't included in multivariable cox regression due to missing data (71.9%). Multivariable cox regression model was only statistically significant for receiving chemotherapy (HR 0.49).

Conclusion: The overall survival of AFP-negative metastatic HCC is very poor. Chemotherapy may be associated with better survival. However, the chemotherapy variable in SEER is limited by data incompleteness and possible unmeasured causes for receiving or not receiving chemotherapy. It is unclear if patients with negative AFP metastatic HCC survive longer than those with positive AFP metastatic HCC. More studies are needed to study the effect of different biomarkers on the survival of HCC patients.

CHRONIC LIVER DISEASE AND RADIATION-INDUCED SECOND PRIMARY LIVER MALIGNANCY

A. Ellaiithy¹, I. Ellaiithy²

¹Suez Canal University, Faculty of Medicine, Ismailia, Egypt,

²Cairo University, Faculty of Medicine, Cairo, Egypt

Contact E-Mail Address: asmaa.ellithy1@gmail.com

Introduction: Cancer survivors are at a high risk to develop second primary malignancy (SPM) which constitutes a serious threat for them. Radiotherapy is the cornerstone for the management of many cancers as a loco-regional treatment modality. Due to the low liver tolerance, cirrhotic patients are at a high risk of developing radiation-induced liver toxicities despite the modern safe radiation delivery techniques. Radiation damage cells through direct energy deposition and reactive free radical generation. Recent studies demonstrated a potential risk of SPMs following radiotherapy with further investigations for strategies to decrease radiation-induced SPMs. However, it is insufficiently addressed if developing liver SPMs is a serious adverse event following radiotherapy for cirrhotic patients.

Aims & Methods: We aimed to quantitatively assess the risk of gastrointestinal (GI) and liver SPMs following radiotherapy in patients with chronic liver disease. SEER.stat version 8.4.3 was used to obtain and analyze the data of patients with chronic liver disease diagnosed from 2000 to 2020. Using Ishak fibrosis score: F0-4 for no to moderate fibrosis and F5-6 for advanced or severe cirrhosis. We subgrouped the patient according to the history of receiving radiotherapy for prior cancer treatment in two groups and excluded patients with unknown radiotherapy administration history. We used MP-SIR session to calculate the Standardized Incidence Ratio (SIR) as Observed/Expected (O/E) with 95% confidence interval (CI). We calculated the Excess Risk (ER) per 10,000. Significance was achieved at 0.05.

Results: Out of 15,168 patients with advanced liver cirrhosis, 88.4% received no radiotherapy and 11.6% received systemic radiotherapy. We observed 215 cirrhotic patients developed GI SPMs (O/E=2.76, 95%CI: 2.41-3.16, P<0.05, ER= 45.51), 106 of them developed liver SPMs (O/E=8.80, P<0.05). Patients with liver cirrhosis who received radiotherapy had an increased risk for GI SPMs (Observed=24, O/E=3.34, 95%CI: 2.14- 4.96, P<0.05, ER= 64.43) compared to who received no radiotherapy (O/E=2.71, 95%CI: 2.34- 3.12, P<0.05, ER= 43.72). Liver SPMs after radiotherapy in cirrhotic patients had an O/E of 12.31 (Observed=13, P<0.05) while the group who received no radiotherapy had an O/E of 8.46 (Observed=93, P<0.05, ER=29.77). In non-cirrhotic patients, we observed 75 patients had GI SPMs with O/E of 3.13 (P<0.05), 30 of them had liver SPM (O/E= 8.44, P<0.05) and five patients had intrahepatic bile duct SPM (O/E= 10.59, P<0.05).

Conclusion: The results of this study give deep insights regarding the burden of SPMs in chronic liver disease. Liver cirrhosis with or without radiotherapy exposure have significantly increased the risk for GI SPMs. Cirrhotic patients who received radiotherapy had an increased risk for GI SPMs by three folds and a 12-fold increased risk for liver SPMs. However, who received no radiotherapy had an 8-fold increased risk for liver SPM. Thus, screening for HCC and GI SPMs in cirrhotic patients is a must for early detection and better management outcome especially after radiotherapy.

FIB-4 IN PREDICTING HEPATOCELLULAR CARCINOMA DURING VIRAL HEPATITIS: A NOVEL INDICATION FOR AN OLD TOOL

M. Ayari¹, A. Chehaider¹, W. Khemiri¹, M.H. Douggu¹, T. Jomni¹

¹Internal Security Forces Hospital La Marsa, Gastroenterology, Tunis, Tunisia

Contact E-Mail Address: ayari.myriam@hotmail.fr

Introduction: Hepatocellular carcinoma (HCC) is a severe outcome during liver disease with limited treatment options when diagnosed lately. It is the leading cause of death in patients with chronic hepatitis, particularly secondary to chronic viral hepatitis. Screening scores are continuously being developed and assessed to optimize early diagnosis.

Aims & Methods: The aim of this study was to investigate the correlation between FIB-4 score and HCC risk during treated chronic viral hepatitis in Tunisian patients. We conducted a single-center retrospective study analyzing data from patients with chronic viral hepatitis B and C. Patients with co-infection BD, D, VIH or associated nonalcoholic steatohepatitis were excluded. FIB4 score was calculated for each patient at presentation.

Results: In total, 88 consecutive patients were enrolled: 42 with chronic hepatitis B and 46 with chronic hepatitis C. The mean age at diagnosis was 51.5 ±12 years with a sex-ratio M/F of 1.31. At baseline, 37.2% of patients had already developed cirrhosis. Virological response was achieved in 92% of the population. HCC occurred in 16% (N=14) of patients after a mean follow-up period of 79. The stage of HCC was classified as 'A', 'B', 'C' and 'D' according to BCLC classification in 28.5%, 25%, 43% and 0.7% respectively. Univariate analysis identified: older age (p=0.02), low platelet count (p<0.0001), cirrhosis (p<0.0001), high bilirubin level (p=0.028) and high Fib-4 (p=0.01) as factors associated with the occurrence of HCC. When analyzing the receiver operating characteristic (ROC) curve, AUC of FIB4 score in predicting HCC was 0.845 (95% CI: 0.730–0.960, p<0.0001). The corresponding FIB-4 cut-offs for 90% sensitivities was 1.67, while the cut-offs for 90% specificities was 3.8.

Conclusion: In our study, high FIB-4 score was associated with increased HCC risk in patients with viral hepatitis. FIB-4 index is based on routinely clinical and biological data and showed highly predictive performances in predicting HCC allowing better stratification.

Introduction: Pancreatic Cancer (PC), a highly lethal malignancy of the digestive system, is associated with a poor prognosis, as evidenced by a less than 7% 5-year survival rate [1]. Projections suggest that by 2030, PC will rank as the second leading cause of cancer-related deaths [2-3]. A crucial aspect of the progression of pancreatic cancer involves its crosstalk with endothelial cells (ECs), particularly in the regulation of vascular homeostasis [4]. Numerous studies have demonstrated the significant involvement of Vascular Endothelial Growth Factor (VEGF) in the process of ECs functional remodeling [5-6]. Activation of the PI3K/AKT signaling pathway has been shown to enhance VEGF-mediated vascular formation, thereby contributing to the normal development and repair of the vascular system [7-8]. Considering the aberrant vascular features observed in tumors, targeting specific pathways to revert immature and unstable vessels to a normal vasculature state appears to be a promising therapeutic strategy for the treatment of the disease. Previous studies have indicated that the combination of Formononetin and Salvianolic acid B (FcS) significantly inhibits pancreatic xenograft tumors *in vitro*. However, it remains unclear whether this combination can inhibit the abnormal vascularization of pancreatic tumors to achieve its anti-cancer effect.

Aims & Methods: This study aimed to investigate the efficacy of FcS in modulating the effects of pancreatic cancer on endothelial cells, explore the alterations in molecular mechanisms within these cells, and elucidate the intricate molecular mechanisms underlying this interaction.

To elucidate the interaction between endothelial cells and pancreatic cancer cells, a co-culture system using Human Umbilical Vein Endothelial Cells (HUVECs) and PANC-1 cells was established to investigate the potential of targeting abnormal vasculature as a promising avenue for anti-tumor therapy. The proliferation, migration, invasion, and lumen formation of HUVEC were compared in mono-culture (HUVECs) and co-culture with PANC-1 (H-P), followed by treatment of H-P with FcS to assess its anti-angiogenic properties. Then, molecular docking was utilized to predict the interactions between Formononetin and Salvianolic acid B with RhoA, and the expression of RhoA in HUVECs post-FcS treatment was assessed. Furthermore, the role of RhoA in the effects of FcS on HUVECs was explored using shRhoA lentivirus. *In vivo* investigations were conducted using a zebrafish xenograft tumor model to assess the anti-tumor effects of FcS, focusing on cancer cell proliferation, migration, apoptosis, and vascular sprouting.

Results: The treatment with FcS showed a dose-dependent inhibition of PANC-1-induced alterations in HUVECs, including proliferation, migration, invasion, and tube formation. Molecular docking analysis indicated potential interactions between FcS and RhoA. FcS downregulated the expression of RhoA and modulated the PI3K/AKT pathway in PANC-1-induced HUVECs. Furthermore, the inhibitory effects of FcS on HUVEC phenotypic changes were attenuated by RhoA knockdown. *In vivo* experiments using a zebrafish xenograft model demonstrated the anti-tumor effects of FcS, including the inhibition of proliferation, metastasis, and vascular sprouting, and promotion of tumor cell apoptosis.

Conclusion: This study illuminates the potential of FcS in inhibiting pancreatic cancer-induced changes in endothelial cells. FcS exhibits pronounced anti-abnormal vasculature effects, potentially achieved by downregulating RhoA expression, inhibiting the PI3K/Akt signaling pathway.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) has poor prognosis. This bleak outlook is due to the lack of effective drug therapies for PDAC. Therefore, there is an urgent need to develop new and effective medications for PDAC.

Protein kinase R (PKR) is a ubiquitously expressed serine-threonine kinase encoded by EIF2AK2 in humans. Recent studies have uncovered a dual role for PKR in cancer; it can act as either a promoter or suppressor, depending on the type of cancer. This paradoxical effect is thought to be due to variations in PKR expression and their diverse effects on cellular regulation in different tumor microenvironments.

Our study also revealed that PKR promotes the growth of hepatocellular carcinoma cells infected with hepatitis C virus. However, the role of PKR in PDAC remains to be elucidated.

Aims & Methods: This study aimed to identify the roles and mechanisms of action of PKR in PDAC by analyzing clinical evidence and *in vitro* data obtained from PDAC cell lines.

We used the human pancreatic cancer cell lines (PANC-1 and MIA PaCa-2) and verified PKR expression in PDAC cell lines using RT-PCR and Western

blotting. MTS assay was used to determine the effect of PKR on cell proliferation. To elucidate the mechanisms underlying the effect of PKR on PDAC, RNA-seq analysis was conducted. Flow cytometry was performed to investigate the effects of PKR knockdown on cell cycle progression and apoptosis in PDAC cells.

Additionally, we used the GEPIA database to compare the expression levels of PKR (EIF2AK2) in pancreatic cancer and normal pancreatic tissues. The Kaplan-Meier Plotter tool was used to analyze the relationship between individual PKR mRNA expression and disease-free survival (DFS) in patients with PDAC.

Results: PDAC cell lines exhibited significantly reduced proliferation when transfected with PKR-targeting siRNAs or treated with PKR inhibitors. RNA-seq analysis revealed a substantial upregulation of GADD45A expression when PKR expression was inhibited. After PKR silencing, cell cycle analysis indicated a pronounced accumulation of cells in the G1 phase, which is consistent with the known role of GADD45A as a cell cycle regulator.

Additionally, the inhibition of proliferation resulting from PKR knockdown was reversed upon downregulation of GADD45A, indicating an interactive effect between PKR and GADD45A in regulating PDAC cell growth. Furthermore, as mentioned above, PKR knockdown increased the percentage of cells in the G1 phase, and knockdown of both GADD45A and PKR returned the percentage of cells in the G1 phase to the same level as that in the control. These results indicated that the interaction between PKR and GADD45A plays a critical role in the proliferation of PDAC cells by regulating the cell cycle.

PKR mRNA expression levels in tumor and normal tissues were compared using the GEPIA database. Elevated PKR mRNA expression in tumor tissues compared with that in normal tissues was more pronounced in PDAC than in other carcinomas. We performed a prognostic analysis using the Kaplan-Meier Plotter database to explore the clinical significance of PKR in PDAC. The results showed that patients with elevated PKR mRNA expression had shorter disease-free survival (DFS; n=278; HR=1.84, 95% CI 1.36-2.5). In contrast, the group with high GADD45A expression showed a prolonged DFS. These data were consistent with our *in vitro* experimental results.

Conclusion: PKR promotes PDAC cell proliferation by modulating cell cycle via regulation of GADD45A expression. These results suggest that PKR is a potential novel therapeutic target for PDAC.

Introduction: Over the last two decades, there has been a rise in the diagnosis of Branch Duct Intraductal Papillary Mucinous Neoplasms (BD-IPMN), incidental findings posing potential neoplastic risks. Multiple guidelines, notably the International Association of Pancreatology (IAP)' revised in Fukuoka in 2017, have been suggested to optimize risk manage-

ment. However, the intricate nature of these guidelines makes adherence challenging, raising uncertainties regarding their application in clinical practice.

Aims & Methods: This study aimed to assess adherence to the 2017 IAP guidelines, identify factors associated with non-compliance, and analyze the impact of divergent strategies on clinical outcomes and costs. Clinical and histopathological data from 2017 to 2023 were retrospectively collected from four tertiary centers in Northern Italy, focusing on patients with suspected BD-IPMN. Multivariate logistic regressions were employed to analyze factors influencing divergent strategies from the IAP guidelines and assess their consequences on clinical outcomes, survival, and costs. Surveillance strategies were considered aggressive if deviating to a narrower surveillance timing or indicating higher-level examinations than recommended by the IAP guidelines. Conservative approach was defined as suggesting extended surveillance timing or indicating lower-level examinations than specified by the IAP.

Results: Of the 333 enrolled patients with a total of 1400 visits and a median follow-up of 4 years, 54% received recommendations deviating from the guidelines, predominantly in an aggressive direction (53.7%). Protective factors for deviation were an Age-adjusted Charlson Comorbidity Index (ACCI) above 4 (OR 0.44, 95% CI 0.33-0.58, $p < 0.001$) and larger initial IPMN size (OR 0.22, 95% CI 0.17-0.28, $p < 0.001$), while divergent approach increased by 25% every two years of follow-up (OR 1.25, 95% CI 1.11-1.41, $p < 0.001$). Conservative divergences, occurring in 25% of cases, were associated with the presence of High-Risk Stigmata (HRS) (OR 5.79, 95% CI 1.82-18.50, $p = 0.003$) and female gender (OR 1.55, 95% CI 1.25-2.04, $p = 0.001$). Notably, divergent strategies did not lead to different rates of IPMN-related mortality (2.5% vs 2.4%, $p = 1$). However, they resulted in increased surveillance costs, escalating from 720 [407-1253] to 878 [664-1181] euros per patient over three years ($p = 0.001$).

Conclusion: In conclusion, adherence to the IAP guidelines in clinical practice was low, predominantly exhibiting deviations in an aggressive direction. This non-adherence significantly increased costs compared to those projected by following the recommended guidelines.

Introduction: The combination of standard chemotherapy and phosphorus-32 (^{32}P) microparticle intra-tumoural implantation has revealed encouraging results for patients with locally advanced pancreatic cancer (LAPC). As no direct comparison has been made, our aim was to compare FOLFIRINOX alone and FOLFIRINOX with ^{32}P implantation in a propensity-score weighted analysis.

Aims & Methods: We conducted a retrospective cohort study comparing LAPC patients with combination chemotherapy and ^{32}P implantation at 2 centres with patients with chemotherapy only (discussed at hepatobiliary multidisciplinary team meetings or underwent diagnostic endoscopic ultrasound for pancreatic cancer) from a single centre, from August 2017 to January 2023. Landmark analysis was used to overcome immortal time bias. Propensity score weighting was further performed to minimise baseline confounders. Primary outcome was overall survival.

Results: 104 patients were considered. The landmark date was designated as 3 months after initiation of chemotherapy. After excluding patients who died before the landmark, 101 patients were included in the propensity-score weighted analysis (35 with ^{32}P implantation and chemotherapy, 66 with chemotherapy only). The restricted mean survival time (RMST) within 24 months after initiation of chemotherapy was estimated to be 112 days longer for patients with ^{32}P implantation and chemotherapy (459 days, 95%CI 393-536) compared to patients with chemotherapy only (347 days, 95% CI 308-392). The restricted mean local progression free time within 24 months after initiation of chemotherapy is estimated to be 112 days (95% CI 36-187) longer for patients with ^{32}P implantation and chemotherapy compared to patients with chemotherapy only. Average tumour size at 6 months was 12.8mm smaller (95% CI 4.69-20.9, $p=0.002$) with combination therapy than with chemotherapy only. The probability of downstaging if all patients were to be treated with combination therapy was 22.3% higher (95% CI 5.12%, 39.5%, $p=0.03$) than the probability with chemotherapy only.

Conclusion: This first comparative study between standard chemotherapy and chemotherapy with additional ^{32}P microparticles implantation has demonstrated significant survival, disease control and downstaging benefits of combination therapy with chemotherapy and ^{32}P microparticle implantation.

Disclosure: None.

Introduction: The recent phase IIIb/IV PREDICT trial (NCT03468335) aimed to investigate the predictive value of 1st line chemotherapy (CTX, Gem-nabPac) for 2nd line CTX (nal-IRI/5-FU/FA) in metastatic PDAC patients (mPDAC Pts) and found an association of clinical parameters (e.g. CA19-9 level, leukocyte/neutrophil count) with 2nd line CTX time-to-treatment failure (TTF). Hence, this study had the objective to uncover molecular and phenotypic alterations within the tumor immune microenvironment (TiME) of treatment-na  ve Pts with shortest (S-) vs. longest (L-) TTF after 2nd line CTX and to identify corresponding liquid biomarkers (combined with clinical parameters) for predicting 2nd line CTX TTF.

Aims & Methods: Pts were stratified into two cohorts based on S- or L-TTF2 (n = 10 Pts per group, 80/20% quantiles, TTF2: 2nd line treatment start to treatment failure). PDAC tissue specimens from surgical resection (treatment-na  ve) were enriched for tumor cell content via laser microdissection and subjected to RNA (NanoStringTM, PanCancer IO360) profiling. Selected differentially regulated genes from the Omics results were used for screening PBMCs from 2nd line treatment-na  ve Pts on protein (flow cytometry, FC) or RNA (RT-qPCR) level. FC data was used for the generation of HyperGates (HG) via R-based single-cell clustering algorithms (x-Shift, FlowSOM, T-REX) and subsequent ML-based back-gating (HyperFinder in FlowJo) of most differential clusters. The Weka-based algorithm Wrapper-SubsetEval (WSE) with one of ten different classifiers (NB, KLR, LR, SMO, IBk, RT, RF, J48, FT, SPegasos) was used for feature selection and the classifier/subset with the best performance was used for classification (S-TTF vs. L-TTF, TTF: diagnosis mPDAC to failure of 2nd line CTX) of training (80%, n = 66) as well as validation (20%, n = 16) datasets.

Results: Comparisons of L-/S-TTF transcriptome data revealed significantly increased inflammation (upregulated 18-gene inflammation signature), immune cell activation (enriched signatures: activated CD8 T cells/B cells/CD4 T cells), immune cell infiltration signatures (CD8 T cells, Neutrophils, Tregs), and immune exhaustion (upregulation of PDCD1, LAG3, CTLA4, TIGIT, IDO1, CD96) for L-TTF tumors. Additionally, the favorable Bailey immunogenic subtype was enriched for the L-TTF group. Hence, PBMCs from blood samples of 2nd line CTX na  ve mPDAC Pts were screened for selected differentially regulated candidates from the Omics results. Analysis of eight separate FC panels including 19 candidates revealed 1198 differential clusters with corresponding HGs. Feature selection for this dataset combined with 50 additional features from RT-qPCR (relative expression and ratios for 12 candidates), 890 manual (classical) gates (MGs) for FC data, and 45 clinical parameters, unmasked a signature of 7 HGs and 2 MGs for 9 protein markers (CD4, CD62P, CD8, NKG2D, CD45, CD62L, CD121b, CD19, Nkp46). ML by using Na  ve Bayes successfully predicted S-TTF and L-TTF groups prior to 2nd line CTX with nal-IRI/5-FU/FA (ROC-AUC (training) > 0.90, ROC-AUC (validation) > 0.90).

Conclusion: In our study, we have identified a favorable TiME for L-TTF mPDAC Pts (2nd line CTX) showing CD8 T cell inflamed ("hot") tumor tissues prior to 2nd line CTX. We further present a 9-marker liquid biomarker panel including 9 flow cytometry PBMC population gates for early prediction of 2nd line nal-IRI/5-FU/FA therapy success in mPDAC Pts. With our findings, we aim to advance the personalized treatment of mPDAC Pts e.g. by additionally exploring the potential for immunotherapy in patients with a positive marker signature.

Introduction: The complex biology of pancreatic ductal adenocarcinoma (PDAC) remains a significant challenge and limits overcoming its dismal prognosis. The tumor microenvironment (TME), shaped by dynamic interactions between cancer-associated fibroblasts (CAFs), immune and tumor cells, plays a crucial role in PDAC pathogenesis. Our investigation into homologous recombination deficiency (HRD), caused by mutations in genes like *ATM*, revealed its role in promoting PDAC aggressiveness and triggering a pronounced desmoplastic reaction, suggesting a unique TME programming. We have shown that the loss of *ATM* in the neoplastic epithelium reprograms CAFs through the TGF β signaling to promote cancer aggressiveness. Additionally, preliminary data revealed distinct immune profiles in *ATM*-deficient and proficient tumors.

Aims & Methods: To capture the immune profiles of *ATM*-deficient PDACs, and decipher specific oncogenic tumor-stroma interactions, we first conducted single cell-resolved multiomics analyses of murine *ATM* and/or *P53*-depleted PDACs. Histopathological analyses and validation using publicly available human datasets were performed to further characterize *ATM* loss-specific immune patterns in pancreatic cancer.

Results: Mouse tumor analyses, using single-nucleus multiomics RNA/ATAC sequencing and multiplex immunostainings, revealed alterations in immune cell contents, e.g. reduced macrophage populations and reduced M2 polarization in *ATM*-deficient tumors. *ATM* loss-specific immune molecular signatures were further investigated and correlated with human PDAC RNA sequencing data (TCGA, PanCancer Atlas). Molecular signatures and cell-cell communication inference revealed *ATM*-specific tumor-TME interactions and identified the TGF β signaling as a core driver of the interplay between CAFs, immune cells, and a particularly aggressive EMT-like tumor cell subpopulation overrepresented in *ATM*-depleted tumors. Strikingly, we also observed distinct communication patterns between CAFs and immune cells. Finally, a combinatorial therapy targeting the TGF β -driven tumor-stroma dialog reversed the cancer-promoting TME remodeling and exacerbated the therapeutic response to FOLFIRINOX *in vivo*, exclusively in *ATM*-deficient HRD PDACs.

Conclusion: Through single cell-resolved multiomics analyses of *ATM*-deficient PDACs, and validation in human cases, we unveil transcriptional, translational, and secretory regulatory events, shed light on the intricate interplay between tumor genetics and PDAC microenvironment, and pave the way for the elaboration of novel personalized therapies.

Introduction: FOLFIRINOX and Gemcitabine/Nab-paclitaxel are widely used 1st-line regimens in metastatic pancreatic cancer. We would like to present real-world data of 12 years of experience with both regimens including genomics insights

Aims & Methods: Patients with metastatic pancreatic cancer who received FOLFIRINOX or Gemcitabine/Nab-paclitaxel were retrospectively included from January 2010 to December 2022. Outcomes were overall survival (OS) and progression free survival (PFS). Median survival time was calculated using Kaplan-Meier estimates adjusted with 1:1 Propensity Score Matching (PSM). Additional tissue Next Generation Sequencing (NGS) panel data was analyzed.

Results: A total of 521 patients, 251 patients received FOLFIRINOX and 270 patients received Gemcitabine/Nab-paclitaxel as a first-line regimen. FOLFIRINOX group were younger (61.8 vs. 65.9, $p < 0.001$). Before PSM, FOLFIRINOX group showed prolonged median OS (11.1 vs 7.8 months) and PFS (8.8 vs. 5.8 months) ($p = 0.002$, both) compared to Gemcitabine/Nab-paclitaxel group. After PSM, FOLFIRINOX group still showed prolonged median OS (11.1 vs 9.0 months, $p = 0.010$) and PFS (9.2 vs 6.4 months, $p = 0.001$) than Gemcitabine/Nab-paclitaxel group. NGS was available from 31 and 22 patients in the FOLFIRINOX and Gemcitabine/Abraxane group, respectively. The most frequently mutated genes were KRAS (94.3%), TP53 (84.9%), CDKN2A (24.5%), SMAD4 (24.5%), ARID1A(13.2%) and RNF43(9.4%). On Cox Regression Analysis, RNF43 mutation was correlated with poor PFS with Gemcitabine/Nab-paclitaxel (HR, 4.849; 95% CI, 1.150-20.450, $P = 0.032$).

	FOLFIRINOX (N = 31)			Gemcitabine/Nab-P (N = 22)		
	cHR	95% CI	P value	cHR	95% CI	P value
KRSA	2.577	0.597-11.115	0.204	1.602	0.209-12.279	0.650
TP53	1.922	0.576-6.414	0.288	1.122	0.363-3.464	0.842
CDKN2A	1.698	0.708-4.074	0.236	1.103	0.409-2.973	0.846
SMAD4	0.678	0.274-1.677	0.400	0.701	0.264-1.860	0.475
ARID1A	0.670	0.158-2.848	0.588	1.919	0.610-6.034	0.265
RNF43	1.199	0.276-5.210	0.809	4.849	1.150-20.450	0.032

cHR, Crude hazard ratio; CI, confidence interval

Conclusion: FOLFIRINOX showed prolonged OS and PFS compared to Gemcitabine/Nab-paclitaxel. FOLFIRINOX can be considered 1st-line regimen in metastatic disease. The NGS data suggest RNF43 could be a potential predictive marker for the response to Gemcitabine/Nab-Paclitaxel, however, larger size confirmation study is needed to validate this finding.

Disclosure: Nothing to disclose.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is a lethal malignancy with a devastating prognosis. A lack of durable responses to chemotherapy renders its treatment particularly challenging. Gemcitabine, a pyrimidine anti-metabolite, is a key component in PDAC therapy, but resistance poses a major hurdle in clinical care. Multiple mechanisms of chemoresistance have been attributed to rewired metabolism in PDAC cells. Accordingly, we aim to target these altered metabolic pathways to improve response to treatment.

Aims & Methods: To investigate metabolic vulnerabilities, we generated an acquired gemcitabine resistance in murine PDAC cell lines. We performed RNA sequencing on parental and gemcitabine resistant cell lines to identify targetable transcriptomic programs that drive cell-intrinsic resistance.

Results: Our transcriptomic dataset demonstrated that PDAC cells re-wire several metabolic pathways upon the acquisition of gemcitabine resistance, including downregulation of nucleoside transporters required for gemcitabine uptake and gemcitabine activating enzymes, as well as upregulation of detoxification enzymes. We performed a customized screen of common metabolic inhibitors and observed that gemcitabine resistant cells were exquisitely susceptible to statins, inhibitors of the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, an observation consistent across multiple clinically available statins. Protein and RNA sequencing data showed a downregulation of the mevalonate biosynthesis pathway and its rate-limiting enzyme, HMG-CoA reductase, in gemcitabine resistance. Importantly, the sensitivity to statins correlated with the extent of the gemcitabine resistance, suggesting that targeting the HMG-CoA reductase is a metabolic vulnerability that is gradually gained in PDAC cells upon the acquisition of resistance. Downstream rescue experiments suggested that statins induce apoptosis through lowered levels of geranylgeranyl pyrophosphate and reduced protein geranylation of small GTPases. To validate our findings *in vivo*, we orthotopically implanted gemcitabine resistant murine PDAC cells into syngeneic mice that were fed with a modified diet precluding geranylgeraniol. Here, the combined treatment of gemcitabine and pitavastatin effectively inhibited tumor growth of resistant allografts.

Conclusion: Collectively, these data suggest that targeting the HMG-CoA reductase is a metabolic vulnerability that is gained in PDAC cells upon the acquisition of gemcitabine resistance. The treatment combination of gemcitabine and pitavastatin, two widely used compounds in patients, has potential to translate into an immediate clinical benefit and improve survival in this deadly disease.

Introduction: Eosinophilic esophagitis (EoE) is a chronic inflammatory and progressive fibrotic condition of the esophagus characterized by the infiltration of eosinophils into the esophageal mucosa and esophageal dysfunction. There remain limited treatment options for EoE and accordingly, a substantial unmet need for effective and safe medical therapies. Drug development in EoE has been hampered by heterogeneous placebo response rates, especially for clinical outcomes, and uncertainty regarding appropriate endpoint configurations. Accurate characterization of placebo response in EoE randomized controlled trials (RCTs) will help inform more future efficient trial designs.

Aims & Methods: To conduct a systematic review and meta-analysis to characterize symptomatic, endoscopic, and histologic placebo response rates in placebo controlled EoE RCTs.

Electronic database (CENTRAL, MEDLINE, EMBASE) searching (inception to 1 JAN 2024) identified placebo controlled RCTs evaluating medical therapies for adults with EoE. Studies were screened independently by 2 reviewers (AR and SA), and full texts were then reviewed for eligibility. The proportion of clinical, endoscopic, and histologic responders (improvement and remission) assigned to placebo were pooled using a random-effect model. The Stuart-Ord inverse double arcsine square root transformation method was used to compute 95% confidence intervals (CI) for point estimates of placebo response. Heterogeneity was evaluated using the *I*² method. Analyses were conducted in StatsDirect 3.3.6.

Results: A total of 25 placebo-controlled RCTs (placebo sample size range: N = 4–105) were included. The pooled proportion of patients receiving placebo who achieved clinical response was 41.0% (n = 11; 95% CI 29.7%, 52.8%) with substantial heterogeneity (*I*² = 74.9%). Definitions of clinical response varied between studies. The pooled proportion for histologic remission (peak eosinophil count [PEC] ≤ 6 eos per high power field [hpf]) was 4.3% (n = 20; 95% CI 2.6%, 6.2%) with low heterogeneity (*I*² = 23.6%), while a more stringent definition of histologic remission (PEC ≤ 1 eos/hpf) yielded a pooled placebo remission rate of 1.3% (n = 18; 95% CI 0.5%, 2.5%) with low heterogeneity (*I*² = 0%). The pooled histologic improvement rate was 6.2% (n = 15; 95% CI 3.3%, 10.0%) with substantial heterogeneity (*I*² = 50.6%). Limited studies reported on endoscopic improvement and remission (Table 1).

Conclusion: More than 1 in 3 patients assigned to placebo in EoE RCTs will achieve clinical response (substantial heterogeneity detected), while less than 1 in 10 of these patients will achieve histologic remission (low

heterogeneity detected). These findings highlight 1) the need to develop validated and responsive patient-reported outcome measures, which may be difficult due to the episodic nature of symptoms in EoE; and 2) the challenge of using a coprimary clinical and histologic outcome in EoE RCTs, given the discordance between symptoms and objective disease activity measures.

Outcome Measured in Placebo Patients (n = number of studies)	Sample Size (range)	Pooled Proportion% (95% CI)	Heterogeneity, I ² % (95% CI)
Clinical Response/Improvement (n = 11)	6 to 105	41.0 (29.7, 52.8)	74.9 (49, 84.8)
Clinical Remission (n = 9)	4 to 33	13.8 (5.9, 24.3)	66.2 (12.2, 81.6)
Endoscopic Response/Improvement (n = 3)	6 to 19	25.1 (12.4, 40.5)	0 (0, 72.9)
Endoscopic Remission (n = 3)	9 to 29	2.8 (0.06, 9.6)	9.1 (0, 75.3)
Histologic Response/Improvement (≤ 15 eos/hpf, n = 15)	6 to 105	6.2 (3.3, 10.0)	50.6 (0, 71.3)
Histologic Remission (n = 24)			
≤ 6 eos/hpf (n = 20)	6 to 105	4.3 (2.6, 6.2)	23.6 (0, 55.2)
≤ 1 eos/hpf (n = 18)		1.3 (0.5, 2.5)	0 (0, 43.7)

Table 1. Pooled proportion of placebo patients achieving measured outcomes in EoE studies.

Contact E-Mail Address: josephcooney@doctors.org.uk

Introduction: Orodispersible budesonide (ODB) is an effective treatment for eosinophilic oesophagitis (EoE), with clinical trials reporting clinical remission rates of 75% at 48 weeks. Real-world data is lacking, particularly for longer term ODB maintenance treatment. We have conducted the first UK multicentre review of real-world outcomes on adults with EoE taking ODB from 5 tertiary hospitals.

Aims & Methods: Databases at 5 UK centres were screened to identify adults taking ODB. Audit approval was obtained by each centre. Electronic results and documentation were reviewed. Patients were telephoned and validated surveys completed to assess symptoms – Reflux Disease Questionnaire (RDQ), Hospital Odynophagia Dysphagia Questionnaire (HODQ) and Adult EoE Quality of Life Survey (EoE-QoLS). A numeric rating scale was used for pts to gauge their response to ODB.

Results: 104pts aged 24-86y (med 41y), 27F:77M, taking ODB for 3-60months (med8.5m, mean14.2m) were included.

97pts completed questionnaires – 98% reported ODB had improved their symptoms. Scores on ODB were low, suggesting clinical remission: RDQ 0-52 (med0), HODQ 0-29 (med2), and EoE-QoLS 37-120 (med60).

71% received PPI first line prior to ODB, of which 81% reported inadequate improvement in dysphagia and 94% did not achieve histological remission (HR, <15eos/hpf) on PPI prior to ODB. 21pts continued PPI in addition to ODB - 1/21 was not in HR.

82pts underwent OGD on ODB – 77% were in HR. 74% pts had fibrotic findings (stricture, trachealisation) which had improved or resolved for 49% on ODB. 78% pts had inflammatory findings (oedema, exudate, furrows) which had improved or resolved for 67% on ODB.

14% experienced oro-oesophageal candidiasis on ODB. ODB was not discontinued.

Following ≥8week induction with 1mg BD ODB, 51pts had tried a reduced maintenance dose of 1mg OD ODB – 77% reported no deterioration in their symptoms on 1mg OD vs BD. 10pts had undergone OGD on 1mg OD – 7/10 were in HR.

Conclusion: Symptomatic and histopathological remission rates on ODB in this multicentre UK study are comparable to clinical trial outcomes yet resolution of endoscopic signs was lower. 1mg OD ODB kept a majority with symptomatic control but this was not always accompanied by histological/endoscopic remission. QoL scores were not proportionately as low as symptom scores on ODB, suggesting a persisting psychological burden despite treatment and warrants further study.

Introduction: Cendakimab is a recombinant, humanized, high-affinity, neutralizing monoclonal antibody that binds to interleukin 13 (IL-13) and blocks interaction with both its receptors, IL-13Rα1 and IL-13Rα2. IL-13 is a cytokine implicated in the pathogenesis of atopic dermatitis (AD) and is thought to be a key driver of the complex pathophysiology of eosinophilic esophagitis (EoE). IL-13 signals through both IL-13Rα1 and IL-13Rα2 to regulate cellular and molecular pathways across a variety of cell types. The binding of IL-13 to IL-13Rα1 promotes a Type 2 immune response and eosinophil recruitment, whereas the binding of IL-13 to IL-13Rα2 is believed to play a role in fibrosis and epithelial tissue remodeling. Several biomarkers associated with Type 2 inflammatory diseases are known to be regulated by IL-13. Eotaxin-3, a key biomarker, plays a central role in attracting eosinophils to the site of inflammation. Periostin, an extracellular matrix protein linked to activated fibroblasts, is implicated in tissue remodeling and fibrosis. Another enzyme governed by IL-13 is matrix metalloproteinase-12 (MMP-12)—this enzyme contributes to tissue remodeling and breakdown of extracellular matrix components. Here, we evaluate the pharmacodynamic effects of IL-13 inhibition with cendakimab on the key serum biomarkers eotaxin-3, periostin, and MMP-12 in patients with AD, with a focus on exploring potential implications for EoE.

Aims & Methods: In this phase 2, multicenter, global, randomized, double-blinded, placebo-controlled, parallel-group study (NCT04800315), 220

adults with moderate-to-severe AD received cendakimab 360 mg Q2W, 720 mg QW, 720 mg Q2W, or placebo for 16 weeks. Blood samples were collected, and a panel of biomarkers were assessed. The current analysis focuses on the assessment of serum levels of eotaxin-3, periostin, and MMP-12 using Proximity Extension Assay pre- and post-treatment on day 1 (baseline), at week 1 and week 2, and then biweekly until week 16. The least square mean percent change from baseline at week 16 for each treatment group was evaluated.

Results: For all 3 doses of cendakimab, there was a significant decrease from baseline in the levels of eotaxin-3, periostin, and MMP-12 as early as week 1 post-treatment and continued through week 16 of cendakimab treatment (Table). Compared with placebo, cendakimab resulted in significantly greater reductions in these biomarker levels through week 16.

Conclusion: Cendakimab decreased levels of key inflammatory and remodeling biomarkers over 16 weeks of treatment in patients with AD. These findings suggest that cendakimab modulates pathways of inflammation, fibrosis, and tissue remodeling in AD and add to the existing clinical evidence of its modulation in other Type 2 inflammatory diseases such as EoE.

Treatment	Eotaxin-3 LS mean percent CFB (95%CI)	Periostin LS mean percent CFB (95%CI)	MMP-12 LS mean percent CFB (95%CI)
Cendakimab 360 mg Q2W	-51.53 (-61.98 to -38.20)*†	-47.50 (-56.45 to -36.73)*†	-52.00 (-58.39 to -44.63)*†

Introduction: Eosinophilic esophagitis (EoE) is a chronic, progressive, type 2 inflammatory disease, with a substantial impact on quality of life; longer disease duration increases the risk of fibrostenosis, which may reduce both clinical and histologic response to therapy. Dupilumab, a fully human monoclonal antibody that blocks key drivers of type 2 inflammation, is approved for the treatment of EoE in adults and adolescents aged ≥12 years weighing ≥40 kg in the EU, and for patients aged ≥1 year, weighing ≥15 kg in the US.

Aims & Methods: The objective of this post-hoc subgroup analysis of the LIBERTY EoE TREET study (NCT03633617) was to assess the long-term efficacy of dupilumab in patients with EoE stratified by baseline disease duration. In Part B, patients received 24 weeks of dupilumab 300 mg once weekly (qw), dupilumab 300 mg once every 2 weeks, or placebo qw. Eligible patients who completed Part B received dupilumab through 52 weeks (Part C). This analysis focuses on patients who were originally randomized to dupilumab 300 mg qw or placebo. Co-primary endpoints were the proportion achieving peak esophageal intraepithelial eosinophil count (PEC) ≤6 eosinophils per high-power field (eos/hpf) and absolute change from baseline in Dysphagia Symptom Questionnaire (DSQ) total score. Key secondary endpoints included proportion achieving PEC <15 eos/hpf, and mean change from baseline in Endoscopic Reference Score (EREFS) total score and Histologic Scoring System (HSS) grade/stage scores. Data were stratified by baseline disease duration defined as time since diagnosis (≤5 years, >5-10 years, >10 years), as reported by the investigator.

Results: At Part B baseline (Week 0) in the dupilumab and placebo groups, respectively, 43 and 48 patients had EoE for ≤5 years, 22 and 13 patients had EoE for >5-≤10 years, and 15 and 18 patients had EoE for ≥10 years. Each of the co-primary endpoints—PEC ≤6 eos/hpf and DSQ total score at Week 24—favored dupilumab over placebo, regardless of disease duration (Table).

At Week 24, marked improvements with dupilumab vs placebo were also seen for EREFS and HSS grade/stage scores across all disease duration subgroups (Table). At Week 52, all patients who received continued dupilumab maintained improvement across all outcomes, including 88.6%, 73.7%, and 90.9% achieving ≤6 eos/hpf in the ≤5, >5-≤10, and ≥10 year subgroups, respectively. Regardless of subgroup, 100% of patients receiving continued dupilumab achieved PEC <15 eos/hpf at Week 52. Patients who switched from placebo to dupilumab at Week 24 showed improvement in all outcomes at Week 52, comparable to patients who received continued dupilumab.

	≤5 years		>5-≤10 years		>10 years	
	Placebo (n=48)	Dupilumab qw/ dupilumab qw (n=43)	Placebo (n=13)	Dupilumab qw/ dupilumab qw (n=22)	Placebo (n=18)	Dupilumab qw/ dupilumab qw (n=15)
Proportion achieving PEC ≤6 eos/hpf, n (%)	4 (8.3)	28 (65.1)	0 (0.0)	11 (50.0)	1 (5.6)	8 (53.3)
Proportion achieving PEC <15 eos/hpf, n (%)	5 (10.4)	37 (86.0)	0 (0.0)	19 (86.4)	1 (5.6)	10 (66.7)
Change from baseline in DSQ score	-14.6 (12.8)	-24.7 (16.5)	-9.3 (8.7)	-23.4 (17.9)	-17.0 (13.9)	-25.9 (15.0)
Change from baseline in EREFS total score	-0.9 (4.2)	-4.7 (3.9)	-0.6 (1.9)	-3.7 (3.0)	-0.1 (2.7)	-4.1 (2.7)
Change from baseline in HSS grade score	-0.1 (0.5)	-0.9 (0.5)	-0.1 (0.4)	-0.9 (0.4)	-0.1 (0.3)	-0.8 (0.5)
Change from baseline in HSS stage score	-0.1 (0.5)	-0.8 (0.4)	-0.1 (0.4)	-0.9 (0.4)	-0.1 (0.3)	-0.7 (0.5)

Data are reported as mean (SD) unless otherwise stated. DSQ, Dysphagia Symptom Questionnaire; eos/hpf, eosinophils per high-power field; EREFS, Endoscopic Reference Score; HSS, Histologic Scoring System; PEC, peak intraepithelial esophageal eosinophil count; qw, once weekly; SD, standard deviation.

Table. Co-primary and secondary endpoints at Week 24, stratified by baseline disease duration.

Conclusion: Dupilumab 300 mg qw demonstrated notable histologic response and substantial symptomatic and endoscopic improvements in adults and adolescents with EoE through 52 weeks. These results show that dupilumab 300 mg qw is an effective long-term treatment for patients with EoE, regardless of disease duration at baseline.

Introduction: Eosinophilic esophagitis (EoE) is a chronic, progressive Type 2 inflammatory disease characterized by esophageal dysfunction and eosinophilic inflammation. Interleukin (IL)-13 is a key mediator in the pathogenesis of EoE. Cendakimab, a humanized monoclonal anti-IL-13 antibody, lowered esophageal eosinophil counts and improved dysphagia, histologic and endoscopic measures of inflammation, and fibrosis in a phase 2 trial of patients with EoE regardless of steroid response. Previous studies have shown that cendakimab reversed the expression of genes and molecular pathways involved in EoE pathogenesis vs placebo, including genes involved in IL-13 signaling, remodeling, and epithelial differentiation. Transcript changes correlated with histological and endoscopic findings.

In this substudy, we performed a detailed analysis of the relationship between endoscopic responder populations and changes in tissue transcript expression.

Aims & Methods: In a double-blind, placebo-controlled phase 2 trial (NCT02098473), patients with EoE received cendakimab 180 mg or 360 mg once weekly or placebo. This substudy evaluated the impact of systemic cendakimab treatment on local esophageal gene expression, as well as correlations between gene expression and endoscopic outcomes (endoscopic reference score [EREFS] range, 0–18). EoE-related transcripts were quantified in biopsies collected at baseline and at week 16.

Results: *POSTN* ($r=0.43$; $P<0.0001$) and *ALOX15* ($r=0.43$; $P<0.0001$) showed the strongest correlation with total EREFS across placebo and cendakimab groups. Endoscopic responders on cendakimab (post-treatment EREFS <2) exhibited improved expression of 33 genes vs baseline. Interestingly, endoscopic nonresponders showed improvement in the same 33 genes plus 6 additional genes (*ALOX12*, *GRPEL2*, *UPK1A*, *SPINK7*, *FAM25A*, *SPRR2D*).

Patients with endoscopic improvement (post-treatment EREFS decrease ≥ 4) showed normalization in a subset of genes ($n=15$, including *TPSB2*/*TPSAB1*, *CPA3*, and *TGFB1*) that did not reverse in patients showing less EREFS improvement. However, patients with less EREFS improvement (post-treatment EREFS decrease <4) showed corrected expression of 2 key epithelial genes, *SPINK7* and *UPK1A*, that did not reverse in patients with endoscopic improvement.

Conclusion: Molecular analysis of biopsies from patients with EoE demonstrates that after 16 weeks of treatment with cendakimab, endoscopic responders and nonresponders both show improvement in gene expression. Heterogeneous changes in inflammatory-, mast cell-, and epithelial-related genes may impact endoscopic findings. These findings indicate that cendakimab broadly modifies molecular biomarkers even in patients who do not show early endoscopic improvement, raising the possibility that biomarker improvement may precede endoscopic changes in some patients.

Introduction: Budesonide orodispersible tablets (BOT) effectively induce and maintain clinical and histological remission in patients with eosinophilic esophagitis (EoE) (1, 2). A substantial fraction of patients recruited for the BUL-1 and BUL-2 studies had previously been treated with swallowed topical corticosteroids (STC) other than BOT. This *post-hoc* analysis aims to assess whether BOT was equally effective in adult EoE patients with and without prior use of STC (3).

Aims & Methods: This retrospective *post-hoc* analysis pooled 59 patients from the double-blind study phase of the BOT induction study (BUL-1) and 181 patients from the open-label induction phase of the BOT maintenance study (BUL-2). Patients were either STC-naïve ($n=103$) or had prior STC ($n=118$); for 19 patients previous treatment with STC was unknown. All patients received 1 mg BOT two times daily (BID) for 6 weeks. The primary efficacy end point was the rate of patients with clinico-histologic remission (≤ 2 points on numerical rating scales [0–10] each for dysphagia and odynophagia on each of the last 7 days prior to the end of treatment [EoT], and peak eosinophil count <16 eos/mm² hpf [corresponding to <5 eos/hpf]) at week 6/EoT.

Results: BOT showed similar efficacy in patients both with and without prior STC treatment. Clinico-pathologic remission was recorded for 67.8% ($n=67$) of patients with prior STC treatment and 65% ($n=80$) of patients with no prior STC (table 1).

Prior STC-treatment	Number (%) of patients achieving clinico-histological remission at week 6/EoT; [total number]		
	BUL-1 (1 mg BID)	BUL-2 (1 mg BID)	Overall
Unknown	2 (66.7) [n=3]	11 (68.8) [n=16]	13 (68.4) [n=19]
No	9 (52.9) [n=17]	58 (67.4) [n=86]	67 (65.0) [n=103]
Yes	23 (59.0) [n=39]	57 (72.2) [n=79]	80 (67.8) [n=118]

Conclusion: This *post-hoc* analysis of the BUL-1 and BUL-2 study program demonstrates that pre-treatment with STC other than BOT does not reduce the likelihood of achieving clinico-histological remission by treatment with BOT.

One explanation for successful induction of remission despite prior STC treatment is that initial relapse on STC may be due to insufficient delivery of STC to the esophageal mucosa, and/or insufficient equivalent dose of alternative topical steroid compound, rather than patients becoming truly corticosteroid-refractory. In addition, the specialized formulation of BOT that delivers budesonide precisely to the esophageal mucosa may also improve adherence, owing to a more standardized and convenient method of administration.

Introduction: Eosinophilic esophagitis (EoE) is a chronic type 2 inflammatory disease with increasing incidence and prevalence. Patients with EoE usually present with symptoms of dysphagia that impact their quality of life. In the 3-part, Phase 3 LIBERTY EoE TREET study (NCT03633617), dupilumab improved histologic, symptomatic, and endoscopic aspects of EoE up to 52 weeks.

Aims & Methods: The aim of this analysis was to assess the effect of dupilumab on symptoms of dysphagia in the 28-week extended treatment period of LIBERTY EoE TREET in patients who switched from placebo to dupilumab at 24 weeks. In Parts A and B, patients received dupilumab 300 mg or placebo weekly (qw) for 24 weeks. Patients who completed Parts A and B entered Part C - a 28-week extended treatment period in which all patients received dupilumab 300 mg qw; patients entering Part C remained blinded to their treatment in Parts A and B. Dysphagia Symptom Questionnaire (DSQ) score and number of days with dysphagia (assessed using the DSQ) were calculated over a 14-day period. Percent change in DSQ score and in number of days with dysphagia from Week 24 through Week 52 vs the Week 24 baseline were assessed for patients who switched from placebo to dupilumab 300 mg qw at Week 24 and or continued on dupilumab 300 mg.

Results: Mean (SD) DSQ score after 24 weeks of placebo was 24.7 (19.6) and 21.5 (18.4) in Parts A (n=37) and B (n=37), respectively. Significant improvements in DSQ score were observed within 4 weeks of the switch to dupilumab 300 mg qw (mean percent reduction: 31.5% and 29.9%). After 28 weeks (at Week 52), mean percent reduction in DSQ score was 63.6% and 59.7%. After 24 weeks of placebo, mean (SD) days with dysphagia was 6.6 (4.7) and 6.0 (4.7) in Parts A and B, respectively. At Week 52, there was a 63.2% and 46.8% mean reduction in the number of days with dysphagia.

Conclusion: In patients who initially received 24 weeks of placebo, weekly treatment with dupilumab 300 mg resulted in rapid (within 4 weeks) and sustained (up to 28 weeks) improvement in symptoms of dysphagia as assessed by the DSQ score. The magnitude of the improvement in dysphagia observed after switching from placebo to dupilumab was similar to that seen at 4 weeks in patients who originally initiated dupilumab in Parts A and B of the study.

Introduction: Eosinophilic Esophagitis (EoE) is a chronic immune antigen-mediated inflammatory disease, characterised by esophageal dysfunction and eosinophilic infiltration. The pharmacological treatments aim to achieve clinical, endoscopic and histological remission. Recently, a new budesonide orodispersible tablet (BOT) has become available, showing in the registration trials great efficacy compared to placebo in inducing clinical, endoscopic and histological disease remission. Only few real-life data are available in EoE setting.

Aims & Methods: This is a multicentre, prospective, observational study, aimed to evaluate in clinical practice (real-life setting) the safety profile and the clinical, endoscopic and histological effectiveness of BOT in EoE patients. Patients diagnosed with EoE, aged ≥ 18 years, treated with BOT 1mg bid as induction treatment for 12 weeks were enrolled. Clinical, demographic and medication data were collected at baseline. BOT treatment outcomes were evaluated after 12 weeks, considering EoE Endoscopic Reference Score (EREFS) for endoscopic appearance, and peak eosinophilic infiltration for histological assessment. Moreover, the Dysphagia Symptom Questionnaire (DSQ) and Health-Related Quality of Life (HRQoL) were also collected in order to evaluate clinical response.

Results: One-hundred and fifty-two patients (121 male; mean age 35) treated with BOT were enrolled, in 8 Italian Centres and 1 Israelian Centre. The most frequent symptoms at diagnosis were dysphagia (N=119, 78%) and food bolus impaction (N=106, 70%). Allergic comorbidities were present in 105 (69%) of patients. 129 patients were previously treated with PPI, with a positive histological response only in 42 (33%). After 12 weeks of treatment, endoscopic remission was achieved in 54% of patients, with a reduction of the mean EREFS score from 3.1±2 to 1.3±1.1 (p<0.0001). Histological remission was obtained in 91% of patients, with a mean peak of 33.3±29.9 of eosinophils/high power field (HPF) at the baseline vs 3.1±11.3 (p<0.0001). The DSQ shows a significant reduction from 20.3±23.5 vs 4.8±9.6 (p=0.001). HRQoL questionnaire score passed from 119.6±41.8 to 140±40.6 (p=0.02), which demonstrates an improvement in quality of life. Main data are resumed in Table 1. Side effects occurred in 22 out of 151 patients (15.6%), but only four of them needed to stop the treatment with BOT.

Study Population	N	%
Males	121/152	80
Symptoms		
Dysphagia	119/152	78
Food Bolus Impaction	106/152	70

EoE Features	N	Baseline	N	After Induction	p
EREFS Score (mean±SD)	144/152	3.1±2	114/152	1.3±1.1	<0.0001
Eosinophils/HPF (mean±SD)	142/152	33.3±29.9	109/152	3.1±11.3	<0.0001
DSQ (mean±SD)	53/152	20.3±23.5	52/152	4.8±9.6	0.001
HRQoL (mean±SD)	50/152	119.6±41.8	44/152	140±40.6	0.02

Conclusion: This study confirms the effectiveness of the treatment with BOT in the induction of EoE remission in a real-life setting, either considering clinical, endoscopic and histologic outcomes. Our data also showed a good safety profile, with a few patients requiring drug interruption. Further investigations are necessary to evaluate BOT effectiveness in the long-term period.

Introduction: Eosinophilic esophagitis (EoE), a chronic, progressive, type 2 inflammatory disease. Dupilumab is a fully human monoclonal antibody that blocks interleukin (IL)-4 and IL-13, key drivers of type 2 inflammation.

Aims & Methods: The aim of this analysis was to assess the impact of dupilumab on caregiver-reported EoE symptoms in children aged 1 to <12 years with active EoE in the placebo-controlled Part A of the Phase 3 EoE KIDS trial (NCT04394351). This analysis was conducted in children randomized to dupilumab higher-exposure or placebo. The Pediatric Eosinophilic Esophagitis Symptom Score (PEESS) version 2.0 (caregiver version) comprises 20 items (items scored 0–4; higher scores indicate greater burden) assessing frequency (11 questions) and severity (9 questions) of symptoms and adaptive behaviors, containing 4 subdomains: dysphagia, nausea/vomiting, gastroesophageal reflux disease, and pain. PEESv2.0 was evaluated at baseline and Week 16 in EoE KIDS; total, frequency, severity, domain (all scored 0–100), and individual item scores were compared in patients treated with dupilumab higher-exposure or placebo. Reported p-values are nominal.

Results: Baseline characteristics were similar in dupilumab higher-exposure (n=37) and placebo (n=34) groups; baseline mean PEESv2.0 total scores were 38.0 and 38.3, respectively. At Week 16, PEESv2.0 total was reduced with dupilumab higher-exposure vs placebo (least squares [LS] mean change [95% confidence interval (CI)] -19.86 [-24.98, -14.74] vs -11.83 [-17.61, -6.05]; LS mean difference [95% CI] -8.03 [-15.39, -0.67], p<0.05). At Week 16, all domain subscores were at least numerically reduced with dupilumab higher-exposure vs placebo with nominal significance observed in LS mean scores for frequency (-22.47 vs -11.88 [p<0.01]), dysphagia (-23.38 vs -13.76 [p<0.05]), and nausea/vomiting (-29.08 vs -15.30 [p<0.05]) domains.

Conclusion: Dupilumab higher-exposure led to improvement in PEESv2.0 total score vs placebo at Week 16 in EoE KIDS. Frequency, dysphagia, and nausea/vomiting domains were improved with nominal significance, though all domains were improved numerically with dupilumab vs placebo.

Introduction: Etrasimod is an investigational, oral, once-daily (QD), selective sphingosine 1-phosphate (S1P)_{1,4,5} receptor modulator in development to treat immune-mediated inflammatory disorders. Etrasimod regulates lymphocyte egress from secondary lymphatic organs and therefore may have promise in the immune cell mediated disease, eosinophilic oesophagitis (EoE).

Aims & Methods: This analysis aimed to investigate the efficacy and safety of oral etrasimod 1 and 2 mg QD vs placebo (PBO) in adults with active EoE. VOYAGE (NCT04682639) was a phase 2 study with a 24-week (wk) randomised, double-blind, PBO-controlled treatment period, followed by a 28-wk extension period. The primary efficacy endpoint was the percentage change from baseline (BL) (%CFB) in oesophageal peak eosinophil count (PEC) at Wk 16. Other efficacy endpoints assessed the effects of etrasimod on histological and endoscopic features and symptoms of EoE, and included proportion of patients (pts) who achieved PEC <15 and ≤6 eosinophils/high power field, absolute CFB in EoE-Histology Scoring System (EoE-HSS) grade and stage scores, EoE Endoscopic Reference Score (EREFS), Patient Global Impression of Severity (PGIS) and Dysphagia Symptom Questionnaire (DSQ; overall and by BL dilation history) at Wk 24. We present the findings from the double-blind treatment period.

Results: We randomised 108 pts with active EoE to etrasimod 2 mg QD (N=41), etrasimod 1 mg QD (N=39) or PBO (N=28); 47.2% of pts were female and BL average duration of EoE was 4.6 years, with 55.6% having a history of oesophageal dilation and 40.0% having prior corticosteroid treatment. Treatment with etrasimod 2 mg QD resulted in a 46.1% decrease from BL in PEC (PBO-adjusted) at Wk 16 (p=0.0103) and statistically significant reductions in %CFB in PEC at Wk 24, and reductions in absolute CFB in EoE-HSS grade and stage scores, EREFS, PGIS and, in pts without

BL dilation history, DSQ score (Table). In etrasimod 1 mg- vs PBO-treated pts, there were statistically significant reductions in %CFB in PEC and absolute CFB in EoE-HSS grade and stage scores at Wk 24. There were no serious treatment-emergent adverse events (TEAEs) reported up to Wk 24; 2 pts discontinued due to TEAEs (Table).

Visit/endpoint	Etrasimod 2 mg QD (N=41)			Etrasimod 1 mg QD (N=39)			PBO QD (N=28)

^a%CFB (mean [SD]) calculated for PEC, and absolute CFB (least squares mean [standard error]) calculated for EoE-HSS grade and stage, EREFS, PGIS and DSQ. All PBO-adjusted differences from PBO are expressed as least squares mean, except %CFB in PEC, which is expressed as the mean difference.

^bp values are from an analysis of covariance model for rank score of %CFB including factors for treatment group, BL history of oesophageal dilation (Yes/No), concurrent PPI therapy (Yes/No), and BL eosinophil PEC (eos/HPF) as a covariate.

^cFull analysis set, includes all randomised pts who received at least one dose of study treatment.

^dp values are from a linear mixed effects model for change from BL including factors for treatment group, visit, interaction of treatment-by-visit, BL history of oesophageal dilation (Yes/No), concurrent PPI therapy (Yes/No), and BL score as a covariate.

^eGrade and stage score ranges from 0–1.

^fScore ranges from 0–9.

^gScore ranges from 0–4.

^hScore ranges from 0–84.

ⁱSafety analysis set, includes all pts who were randomised and received at least one dose of study treatment.

^jSeverity was classified using CTCAE, version 5.0, ie, Grade 1 for mild, Grade 2 for moderate, Grade 3 for severe, Grade 4 for life-threatening and Grade 5 for death related to AE; most AEs were Grade 1 or 2.

^kFirst-dose, transient heart rate reductions and cardiac conduction aberrations are known on-target effects of sphingosine

1-phosphate receptor modulators. Bradycardia events were reported by 3 pts. One event occurred on Day 1 in a pt taking etrasimod 2 mg QD and was classed as Grade 2; one event occurred on Day 3 in a pt taking etrasimod 2 mg QD and was classed as Grade 1; one event occurred at the Wk-24 visit when the pt transitioned from PBO treatment to blinded etrasimod 1 or 2 mg QD (ie, Day 1 of etrasimod) and was classed as Grade 1. Two cases associated with the first etrasimod dose (asymptomatic with unremarkable electrocardiogram findings) resolved without any interventions at Hour 5 of the cardiac monitor procedure. The third case (without documented heart rate measurement) was associated with dizziness and nausea and was reported on Day 3. The pt continued study treatment and all AEs resolved without interventions on Day 23.

^lWhere seriousness was not entered/missing, the event was classified as serious.

^mBalance disorder, Grade 2.

ⁿDysphagia, Grade 2.

^oTEAEs occurred in ≥10% of pts in at least one treatment group.

%CFB, percentage change from baseline; AE, adverse event; BL, baseline; COVID-19, Coronavirus Disease 2019; CTCAE, Common Terminology Criteria for Adverse Events; DSQ, Dysphagia Symptom Questionnaire; EoE, eosinophilic oesophagitis; EoE-HSS, Eosinophilic Oesophagitis-Histology Scoring System; eos, eosinophils; EREFS, Eosinophilic Oesophagitis Endoscopic Reference Score; HPF, high power field; n, number of pts with event; N, number of pts in the treatment group; PBO, placebo; PEC, peak eosinophil count; PGIS, Patient Global Impression of Severity; PPI, proton pump inhibitor; pt, patient; QD, once-daily; SD, standard deviation; TEAE, treatment-emergent adverse event; Wk, Week.

Table. Change from BL (CFB) in PEC at Wk 16 (primary endpoint), additional efficacy endpoints at Wk 24 and a summary of TEAEs up to Wk 24 in the VOYAGE study.

Conclusion: Etrasimod 2 mg QD met the primary histologic endpoint and significantly improved endoscopic features of EoE, overall symptom severity and dysphagia (in pts without dilation history only) at Wk 24 and was well tolerated. This supports further evaluation of etrasimod in EoE.

Introduction: Endoscopic resection (ER) is curative for Barrett's oesophagus-related early-stage oesophageal adenocarcinoma (EAC) without high-risk features, such as lymphovascular invasion (LVI), positive margins (R1), and deep submucosal invasion (T1b sm2-3). Piecemeal endoscopic mucosal resection (pEMR), often used for lesions larger than 15mm, prevents assessment of lateral margins and therefore complicates precise risk estimation for residual EAC at the first post-ER endoscopy. Thus, we investigated alternative clinical factors that could potentially be used to assess the risk for residual and recurrent EAC post-ER.

Aims & Methods: We performed a longitudinal cohort study of patients who underwent ER between 2006-2023. Inclusion criteria were: T1a or well/moderately differentiated T1b sm1 EAC; LVI-, and R0 resection. ER was categorised as pEMR (n=105) or en-bloc ER (n=22 en-bloc EMR, n=9 endoscopic submucosal dissection). The primary outcome was residual EAC at first post-ER endoscopy. Secondary outcomes were residual HGD at first post-ER endoscopy, recurrence of EAC and HGD at any post-ER endoscopy, and remission of EAC, HGD and intestinal metaplasia (IM) at latest endoscopy. Multivariate logistic regression, receiver operating characteristics, chi-squared, and Kaplan Meier analyses were performed to investigate possible associated risk factors.

	Univariate		Multivariate	
	OR (95% CI)	P-Value	OR (95% CI)	P-Value
Age *	0.96 (0.90-1.01)	0.11	0.92 (0.87-0.99)	0.025
Sex, male *	0.96 (0.20-3.38)	0.95	0.40 (0.057-1.92)	0.30
High alcohol consumption (≥14 units weekly) *	0.65 (0.17-3.15)	0.55	0.44 (0.088-2.58)	0.32
Ever smoker *	1.93 (0.70-5.70)	0.21	2.09 (0.62-7.43)	0.24
Percentage of cancerous samples *†	1.25 (1.03-1.52)	0.026	1.32 (1.07-1.66)	0.013
Number of samples taken	1.11 (0.92-1.33)	0.25		
Differentiation *	1.19 (0.48-3.02)	0.71	1.05 (0.37-3.04)	0.93
Stage, T1b sm1 *	3.50 (0.44-22.79)	0.19	11.01 (1.01-106.05)	0.035

Table 1: logistic regression model for residual EAC at the first post-pEMR endoscopy

* : inclusion in multivariate analysis

† : odds ratio for a 10% increase in the percentage of cancerous samples

Bold indicates statistical significance.

Results: The cumulative incidence of recurrence of HGD was higher post-pEMR compared to en-bloc ER (HR = 2.43, 95% CI: 1.1-5.36; $p=0.021$), with residual EAC at first post-ER endoscopy accounting for 35% of such

post-pEMR recurrence. The percentage of pEMR specimens with EAC was an independent risk factor for residual EAC at first post-pEMR endoscopy ($p=0.013$, Table 1). A 53.5% cut-off of involved pEMR specimens was identified as the optimal threshold for residual EAC prediction (specificity=0.68, sensitivity=0.67, AUC=0.66). Indeed, rate of residual ($p=0.013$) and recurrent ($p=0.00041$) EAC were higher when EAC involvement was >50%. However, rates of remission of EAC ($p=0.13$), HGD ($p=0.20$) and IM ($p=0.81$) were unaffected by high EAC burden.

Conclusion: High burden of cancer in pEMR specimens correlates with increased risk of residual and recurrent EAC at post-pEMR endoscopy. Post-pEMR site check is recommended prior to endoscopic ablation, particularly in patients where more than 50% of pEMR specimens show EAC, where repeat ER should be performed in cases of flat subtle lesions. This will ensure eradication of any focus of residual disease and high success rates for treatment of early EAC using endotherapy.

EFFICACY AND SAFETY OF ENDOSCOPIC SUBMUCOSAL DISSECTION IN ELDERLY PATIENTS WITH RELATIVE INDICATIONS OF EARLY ESOPHAGEAL SQUAMOUS CELL CARCINOMA

H. Yan¹, S. Wang¹, J. Yang^{1,2}

¹West China Hospital, Sichuan University, Chengdu, China, ²West China Hospital, Sichuan University, Chengdu, Christmas Island

Contact E-Mail Address: hailin_yan@163.com

Introduction: Endoscopic submucosal dissection (ESD) has been widely used to treat early esophageal squamous cell carcinoma (ESCC). Literature reported that the excellent 5-year survival rate of patients with early ESCC treated by ESD can reach more than 95%¹. However the premise of efficacy of ESD is that the esophageal lesions meet the indications of endoscopic therapy. Patients with absolute indications (AI) refer to those with tumor infiltrating into the epithelial layer (M1) or mucosal lamina propria layer (M2) or differentiation type of high grade intraepithelial neoplasia (HGIN), who have lower lymph node metastasis (LNM) rate than 5.6% and have excellent efficacy and safety of ESD². Patients with relative indications (RI) refer to those with tumor infiltrating into the mucosal muscle layer (M3) or submucosal superficial layer (SM1) but with no clinical evidence of LNM, who have significantly higher risk of LNM, about 8%-53%², and lack high-quality clinical evidence of the efficacy and safety of ESD.

After ESD, if the patients were at high risk of LNM, additional treatment including surgery, radiation or chemotherapy were recommended. However, some elderly patients often presented with multiple underlying ailments, experiencing organ decline that renders them unable to withstand surgical interventions. It's been reported that the overall survival rate of elderly patients with esophageal squamous after surgery is significantly lower than that of non-elderly patients³⁻⁴. There is lack of data reporting on the survival of elderly patients with RI who are at high risk of LNM after ESD.

Aims & Methods: Our target population is elderly patients with relative indications (RI) of endoscopic submucosal dissection (ESD) for esophageal squamous cell carcinoma (ESCC). They are limited on the performance of ESD and additional surgery after ESD because of severe complications and high mortality. We aim to investigate the efficacy, safety of ESD and benefits of additional surgery in these patients. We collected data of tar-

get population who received ESD in a tertiary hospital from January 2015 to March 2019. We divided them into elderly group (age $\geq$ 65 years, n=38) and non-elderly group (age<65 years, n=70).

Results: Two groups had no significant differences in the rates of bleeding (10.5% vs 12.9%, $P=0.517$), perforation (2.6% vs 2.9%, $P=0.938$), stenosis (31.6% vs 25.7%, $P=0.542$), en-bloc resection (94.9% vs 98.6%, $P=0.252$), R0 resection (61.5% vs 73.2%, $P=0.182$), recurrence (5.3% vs 2.9%, $P=0.088$) and metastasis (2.6% vs 2.9%, $P=0.938$). Kaplan-meier (K-M) analysis showed 5-year progression-free survival rate (5-PFS) (88.6% vs 92.4%, $P=0.755$) and 5-year overall survival rate (5-OS) (96.3% vs 94.9%, $P=0.613$) of elderly and non-elderly group. K-M analysis showed 5-OS of patients with and without additional surgery in elderly group (100% vs 94%, $P=0.724$) and non-elderly group (100% vs 95.8%, $P=0.451$). COX regression revealed tumor progression (including recurrence and metastasis) affected the survival of target population ($P=0.001$, HR=46.562 (4.839, 447.994)) independently. Univariate and multivariate analysis found positive horizontal margin(HM) affected tumor progression ($P=0.010$, HR=10.751(1.717, 67.334)) independently.

Conclusion: ESD showed excellent efficacy and safety in elderly patients with RI who didn't benefit significantly from additional surgery.

THE USEFULNESS OF STEPWISE ESD TO PREVENT SEVERE STRICTURE AFTER ESD FOR CIRCUMFERENTIAL ESOPHAGEAL NEOPLASIA

I. Oyama¹, A. Takahashi¹

¹Saku Central Hospital Advanced Care Center, Endoscopy, Nagano, Japan

Contact E-Mail Address: oyama@coral.ocn.ne.jp

Introduction: Recently, ESD has become widespread, making it possible to safely remove large superficial esophageal cancers measuring 5 cm or more. However, severe stricture after circumferential ESD is a remaining major problem. Several treatment methods including local injection, oral administration of steroid, and stent insertion etc., have been reported. However, their effectiveness is insufficient.

We have reported the effectiveness of stepwise ESD to remove residual Barrett's mucosa to prevent metachronous cancer in UEGW2023. And, we expanded the indication of Stepwise ESD for circumferential SCC.

Aims & Methods: The aim of this study is to clarify the usefulness of Stepwise ESD for preventing severe stricture after ESD for circumferential esophageal neoplasias. Subjects were patients with circumferential

esophageal tumors, and underwent ESD at Saku Hospital from Jan. 2006 to Jan. 2024. Seventeen and fifty-one patients had adenocarcinoma (EAC) and Squamous cell carcinoma (SCC), respectively. The patients were divided into the En bloc (EB) group and the Stepwise (SW) group. In the EB group, a circumferential ESD was performed with or without triamcinolone injection. In the SW group, 2/3 of the circumference was resected in the first ESD, and 50–200 mg of TA was locally injected. And, the second ESD was performed 2–3 months later.

Results: Totally sixty-eight patients were enrolled into this study. 55 patients underwent en bloc resection and 13 patients underwent stepwise ESD. There was no significant difference in age, gender and location between two groups.

The mean diameters of the tumor, length of resected specimen and long axis mucosal defect in the EB and the first Stepwise ESD were 59 (30–130) and 50 (36–90) mm ($p=0.23$), 68 (29–150) and 71 (50–100) mm ($p=0.8264$), and 8 (5–15) and 8 (3–9) cm ($p=0.56$), respectively. There was no significant difference. And, the mean duration of ulcer healing in both groups were 137 (42–1028) and 46 (32–120) days ($p<0.0001$). The duration of ulcer healing was significantly shorter in SW group.

In the EB group, 47 of 55 patients developed severe stenosis and underwent EBD, whereas only 1 of 13 patients in the SW group required EBD. The median number of EBDs in both groups were 5 (0–33) and 0 (0–5), respectively (<0.0001).

Conclusion: The number of EBDs in the SW group was significantly less than that in the EB group. And, there were no severe complications. Therefore, stepwise ESD is an excellent treatment method that can prevent severe stenosis after endoscopic resection of circumferential esophageal neoplasia.

Disclosure: Nothing to disclose.

Contact E-Mail Address: luispedroasantos@gmail.com

Introduction: Gastric polyps are detected in approximately 3–6% of patients undergoing routine upper endoscopy. The standard approach to managing most gastrointestinal polyps is through endoscopic polypectomy, although bleeding is a common adverse event. While cold snare polypectomy (CSP) has been reported as a safe alternative to hot snare polypectomy (HSP) for removing small colorectal polyps, further evidence is necessary to validate its effectiveness and safety specifically for gastric polyps.

Aims & Methods: Aim: Compare the efficacy and safety of CSP and HSP for removing small gastric polyps (5–15mm).

Materials and Methods: Cross-sectional study, with a prospective enrollment, including 330 consecutive gastric endoscopic polypectomies conducted in a tertiary center, between January 2021 and December 2023. Patients who underwent either CSP or HSP for gastric polyps ranging from 5 to 15 mm in size were enrolled, while those with underlying polyposis syndromes were excluded. Dedicated snares were utilized for CSP procedures. A 30-day phone survey was carried out to evaluate post-polypectomy adverse events. Statistical analysis was performed using the SPSS software v28.

Results: Overall, 330 gastric lesions in 218 patients were removed through snare polypectomy (CSP-165 lesions; HSP-165 lesions), mainly located in the body (51.5%). The median lesion size was 8.0 mm (IQR 4.0) and 8.0 mm (IQR 3.0) for CSP and HSP, respectively ($p=0.08$), ranging from 5 to 15 mm in both groups. The most common histological diagnoses were hyperplastic (58.2%) and fundic gland (29.4%) polyps. While the complete endoscopic resection rate was 100% in both groups, the *en-bloc* resection rate was slightly higher for CSP (CSP 98.2% vs. HSP 97.6%; $p=0.45$). At histological analysis, the complete (R0) resection rate was equal for both groups (CSP 98.2% vs. CSP 98.2%; $p=1.00$). Immediate bleeding, endoscopically treated, was more common with HSP (CSP 2.4% vs. HSP 3.6%; $p=0.52$). Delayed bleeding occurred exclusively in the HSP group (CSP 0.0% vs. HSP 1.2%; $p=0.16$). There were no perforations or procedure-related deaths. At univariate analysis, piecemeal resection (OR 64.6; 95%CI [3.5-1184.8]; $p=0.005$) was associated with a higher risk of delayed bleeding.

Conclusion: CSP demonstrates comparable effectiveness and potentially greater safety profile compared to HSP for gastric polypectomy. Consequently, CSP was non-inferior to HSP and may serve as an additional option for the removal of gastric polyps sized ≤ 15 mm. Piecemeal resection is a hypothetical risk factor for delayed post-polypectomy bleeding.

DEVELOPMENT AND VALIDATION OF A MODEL FOR PREDICTING ELECTROCOAGULATION SYNDROME AFTER ENDOSCOPIC FULL-THICKNESS RESECTION OF GASTRIC TUMORS

F. Liao¹, J. Liang¹, Y. Huang¹, J. Rong¹, Z. Zhu¹, X. Pan¹, C. Wang¹, S. Long¹, X. Zhou¹, G. Li¹, Z. Yin¹, Y. Chen¹, X. Shu¹

¹First Affiliated Hospital, Jiangxi Medical College, Nanchang University, Nanchang, China

Contact E-Mail Address: 459048754@qq.com

Introduction: Endoscopic full-thickness resection (EFTR) is a new endoscopic technique, which is mainly used to resect gastrointestinal tumors that are difficult to resect by conventional endoscopic resection methods¹. Post-endoscopic submucosal dissection electrocoagulation syndrome (PEECs) is one of the postoperative complications of endoscopic resection², but the incidence and risk factors of electrocoagulation syndrome after endoscopic full-thickness resection (EFTR) are still unclear. The aim of this research was to identify risk factors and develop a predictive nomogram for electrocoagulation syndrome after gastric EFTR.

Aims & Methods: Multivariate logistic regression was used to analyze the risk factors of electrocoagulation syndrome after gastric EFTR. A prediction nomogram was developed based on the above results, and bootstrap was employed for internal validation of the model.

Results: A total of 507 patients who underwent gastric EFTR were included, and the incidence of PEECs was 9.9%. Multivariate logistic regression showed that tumor size ≥ 10 mm, hot biopsy forceps for hemostasis, and operation time were independent risk factors of PEECs. A nomogram based on these risk factors showed good predictive ability, and the area under the ROC curve (AUC) was 0.769 (95% CI: 0.700-0.838). The calibration curve of the predictive model also demonstrated a good fit.

Conclusion: This study developed a predictive nomogram based on tumor size, hemostasis method, and operation time, which was used to identify high-risk patients with electrocoagulation syndrome after gastric EFTR.

ESD FOR DUODENAL TUMORS – ESD VS. HYBRID ESD –

A. Takahashi¹, T. Oyama¹

¹Saku Central Hospital Advanced Care Center, Endoscopy, Nagano, Japan

Contact E-Mail Address: aurevoireurope@yahoo.co.jp

Introduction: ESD is an excellent endoscopic treatment with high en-bloc and R0 resection rate. However, duodenal ESD is technically difficult. And, it has been reported that the perforation rate of duodenal ESD is higher than that of ESD of other organs.

Hybrid ESD, which involves circumferential incision followed by removal of the lesion using a snare, may shorten the operation time, but detailed studies have not been conducted.

Aims & Methods: The aim of this study was to compare the treatment outcomes of ESD and hybrid ESD for duodenal tumors.

The subjects were superficial duodenal tumors that were resected at Saku Central Hospital from Dec.2002 to Dec. 2023, and diagnosed as grade 3 or 4 according to the Vienna classification.

ESD and Hybrid ESD were performed for 16 and 148 patients. Gender (Male/Female), age and location (1st, 2nd, 3rd) of both groups were 18/8, 106/42, 64 (39-84), 62 (37-84) and (4/18/4), 9/119/20, respectively. There was no significant difference.

Results: 1. Paris classification 0-I/IIa/IIb/IIc were 2/17/1/6 and 3/6/0/84, respectively.

2. En-bloc resection rate was 100% (26/26) and 89% (131/148), respectively ($p=0.07$). R0 resection rate was 100% (26/26) and 82% (121/148), respectively ($p=0.01$).

3. Size of tumor and specimen were 20 (5-63) / 9(2-27) and 28 (17-66) / 16 (8-34) mm, respectively ($P<0.001$, $P<0.001$).

4. Duration of procedure was 95 (34-265) and 30 (8-34), respectively ($P<0.001$).

5. Complications: Perforation, delayed perforation and delayed bleeding were 0% and 2.7% (4/148), 3.8% (1/26) and 2% (3/148), 0% and 0.7% (1/148), respectively. There was no significant difference.

6. Local recurrence rate was 0%, 0.7% (1/148), and the only local recurrent case was treated by HOT biopsy.

Hybrid ESD was useful for shortening treatment duration, however the R0 rate were significantly lower. Recently, under water EMR has been applied to the duodenal lesions, and it seems necessary to conduct a comparative study of hybrid ESD and under water EMR in the future.

Conclusion: ESD has excellent R0 resection rate, however it is technically difficult and has long treatment duration. On the other hand, hybrid ESD shortens treatment times but has lower R0 resection rates. Therefore, the indication of hybrid ESD is limited. Further examination including under water EMR should be performed.

Introduction: Endoscopic submucosal dissection (ESD) is the gold standard for superficial gastric cancer. Nonetheless, mastering ESD entails a steep learning curve requiring 30-50 procedures to achieve proficiency. An innovative robotic flexible endoscopic platform may have the potential to expedite the learning curve. The primary goal of this study was to compare a novel flexible endoscopic robotic platform (R-ESD) with conventional ESD (C-ESD) for safety and efficacy of removing large gastric lesions. The secondary aim was to compare beginners and expert performance.
Aims & Methods: A prospective comparative trial was conducted between R-ESD and C-ESD using large gastric lesions in an ex-vivo porcine model from November 2023 to January 2024. Four beginners (no or little endoscopic dissection experience) and four experts (> 500 ESD procedures) were assigned to perform 3 R-ESD and 3 C-ESD each during the study period. All were novices on the flexible robotic platform and underwent the same standardized one-day training. The main outcome measures were overall operative time, dissection speed, rates of en-bloc and curative resection (R0), and perforation. Secondary outcomes assessed the performance of beginners versus experts.

	Beginners	Expert	p
	R-ESD	C-ESD	
N	12	10	
Time (min)	57.8 (17.1)	52.6 (17.4)	0.489
Area (cm²)	42.1 (10.2)	42.9 (7.7)	0.840
Speed (cm²/min)	0.77 (0.20)	0.92 (0.43)	0.293
Perforation	0/12	0/10	1
Muscle Injury	0/12	0/10	1
R0 Dissection	12/12	10/10	1
En bloc Dissection	12/12	10/10	1

Table 1. Comparison between convention endoscopic submucosal dissection (ESD) performed by experts and robotic ESD performed by beginners. Data are reported as mean (standard deviation) value. A comparison was performed by a Two Sample T-Test. Data are reporting as mean (Standard deviation). Abbreviation: ESD=Endoscopic submucosal dissection; C-ESD=Conventional ESD; R-ESD= Robot-assisted ESD.

Results: In the study period forty-two 5x5cm lesions were resected- 22 R-ESD and 20 C-ESD. Overall the R-ESD and C-ESD groups had similar mean operative time (75.0 [SD 26.0] minutes versus 76.5 [36.3] minutes, respectively) and dissection speed (0.65 [0.21]cm²/min R-ESD versus 0.68 [0.48]cm²/min C-ESD; p=0.798). 100% of R-ESD were completed en-bloc

and with an R0 resection, while the C-ESD group had a 95% en-bloc and 85% R0 resection rate (p>0.05). The perforation rate in R-ESD was 0%, compared to 10% in C-ESD cases. While the disparity between experts and novices was notable for C-ESD, within the R-ESD cohort beginners demonstrated better operative times and dissection speeds, with rates of perforation, en-bloc and curative resection (R0) similar to experts, (Table 1).
Conclusion: Robotic ESD using a novel flexible endoscopic robotic platform proved to be safe, feasible, and equally effective as conventional ESD for managing large gastric lesions. The flexible endoscopic robotic platform empowered beginners to achieve safety and efficacy comparable to experts after just three procedures. This platform holds significant potential to democratize ESD, reducing variability among operators and expanding access to endoluminal organ-sparing therapies for patients.

Introduction: The therapeutic goal in inflammatory bowel disease (IBD), which includes Crohn's disease (CD) and ulcerative colitis (UC), is the control of the inflammatory process through drugs (biologic and JAK-inhibitor therapies) that generally have a high cost and may have side effects. Unfortunately, only one-third of patients respond to these treatments and there are no markers that accurately predict this response.

Aims & Methods: The aim of this study was to identify potential serum metabolic biomarkers predictive of response to different drugs for IBD at baseline (before treatment), which could facilitate the selection of the most appropriate therapy for each patient. For this purpose, a prospective

and multicenter study was conducted including CD and UC patients who initiate biologic (anti-TNF, ustekinumab or vedolizumab) or JAK-inhibitor (tofacitinib) therapies. Patients were assessed at 14 weeks to determine if they had achieved endoscopic response, based on the SES-CD and on the endoscopic sub score of the Partial Mayo Score. The analysis of the serum metabolome and deconvolution of the serum lipoprotein profile into 110 fractions were conducted using nuclear magnetic resonance for quantitative differential analysis comparing baseline serum samples of responders compared with non-responders.

Results: A total of 150 patients were included (30 CD anti-TNF, 30 UC anti-TNF, 30 CD ustekinumab, 30 UC vedolizumab, and 30 UC tofacitinib). Table 1 shows a summary of the most relevant results obtained during the metabolomic analysis, which revealed metabolites and lipoproteins (common or drug-specific) with significantly altered levels ($p < 0.05$) in the baseline serum samples of subsequent responders compared to non-responders. Moreover, based on ROC curves, potential biomarkers with good sensitivity and specificity for distinguishing between responders and non-responders before treatment were identified. Finally, our analysis identified alanine, aspartate, glutamate, arginine and butanoate metabolism, and the citrate cycle, as the main baseline altered metabolic pathways that could be associated with the response to IBD treatment.

Study group	Number of Biomarkers*		Best AUC values**
	Metabolites	Lipoproteins	
CD anti-TNF	2	3	0.83; 0.81; 0.78; 0.75; 0.74
UC anti-TNF	1	7	0.88; 0.84; 0.83; 0.77; 0.76; 0.73
CD ustekinumab	4	24	0.96; 0.95; 0.94; 0.91; 0.90; 0.89; 0.87; 0.80
UC vedolizumab	5	8	0.90; 0.79; 0.78
UC tofacitinib	3	8	0.98; 0.96; 0.91; 0.88; 0.87; 0.85

Table 1. Summary of identified potential metabolic biomarkers predictive of endoscopic response to IBD treatment.

*Biomarkers with significantly altered levels ($p < 0.05$) in the baseline serum of responders vs non-responders patients. **AUC corresponding to the biomarkers with the best sensitivity and specificity for distinguishing between responders and non-responders patients before treatment. AUC: Area Under the Curve calculated using the MetabolAnalyst software in univariate analysis; CD: Crohn's disease; IBD: Inflammatory bowel disease; UC: Ulcerative colitis.

Conclusion: The present study represents an effort towards personalized medicine in targeted therapy selection in IBD patients, which is an important unmet need. Although it needs further validation, we were able to identify a number of serum metabolites and lipoproteins with the potential of predicting response to biologic and JAK-inhibitor therapies.

Introduction: Inflammatory bowel disease (IBD) is strongly associated with joint inflammation, as is highlighted by the high prevalence of spondyloarthritis (SpA) in patients with IBD (up to 13%) compared to the general population (0.2-1.6%) [1, 2].

IBD and SpA have many overlapping features, including genetic risk factors, changes in the gut microbiota, and therapies targeting TNF- α , IL-23, or JAK [3].

However, current therapies for both diseases are unable to break the cycle of chronic inflammation, and still a significant proportion of patients fail to respond. Disease heterogeneity likely plays a role in this [4, 5], underscoring the necessity to improve management and refine classification.

Aims & Methods: In this study, 92 inflammation-related proteins were quantified in serum of patients from one IBD and one SpA cohort using the novel Olink proteomics proximity extension assay. Fold changes (FC) in expression with $|\log_2 FC| > 0.5$ were considered meaningful, and false discovery rates (FDR) < 0.05 were considered significant. The IBD cohort existed of 255 IBD patients with (n=155) and without (n=100) self-reported joint complaints [8].

From the patients with joint complaints, 58 fulfilled any of the SpA criteria. The SpA cohort, or SPACE cohort, consisted of 169 patients with chronic back pain (≥ 3 months, ≤ 2 years) of unknown origin [9].

After 2 years of follow-up, 85 patients had proven axSpA. Serum samples were taken at baseline, and 167/169 samples from the SPACE cohort and 241/255 samples from the IBD cohort passed quality control and were included in the analysis.

Results: Thirty-four proteins were differentially expressed between 95 IBD patients without joint complaints and 85 proven axial SpA (axSpA) patients from the SPACE cohort, of which 14 were higher in IBD patients (including 4E-BP1, IFN- γ , TNF, FGF-21, CD8A, and CCL9), and 20 were higher in axSpA patients (including CASP-8, SIRT2, STAMBP, FGF-19, ST1A1, and EN-RAGE). In addition, the immune profile of IBD patients with joint complaints differed from IBD patients without joint complaints: 4E-BP1, CASP-8, STAMBP, SIRT2, AXIN1, and TNFSF14, were significantly upregulated in patients with joint complaints. Of note, if IBD patients without joint complaints were compared to the subgroup of 58 patients with joint complaints who met criteria for SpA, the same proteins showed significant upregulation, suggesting minimal difference between IBD patients with joint complaints who meet or who do not meet SpA criteria. Direct comparison of patients who met and who did not meet SpA criteria within the group of IBD patients with joint complaints indeed showed no noteworthy difference in serum immune profile. Within the SPACE cohort, comparison of patients with chronic back pain with and without axSpA diagnosis also showed no significant difference in serum protein expression.

Conclusion: This study shows that patients with axSpA versus patients with IBD without joint complaints have differing serum immune profiles. Within IBD patients with self-reported joint complaints and within patients with self-reported chronic back pain (from the SPACE cohort), no distinct difference in immune profile is observed, regardless of SpA diag-

nosis. The inflammation signatures of patients with chronic inflammatory diseases should be further investigated to provide insights for enhancing disease management in the future.

Introduction: Microscopic colitis (MC) is an inflammatory condition of the large intestine encompassing the subtypes lymphocytic colitis and collagenous colitis. MC has been linked to various autoimmune conditions, but reports on autoimmune thyroid disorders (AITD) have mostly been cross-sectional and none has included stratified results or corroborated the association with sensitivity analyses.

Aims & Methods: To examine the association of MC and its subtypes with prior diagnosis of AITD, a matched case-control study was performed using the nationwide ESPRESSO cohort in Sweden. Diagnosis of AITD was ascertained from either ICD-based records of Graves' disease or Hashimoto-specific prescribed drugs. All biopsy-confirmed MC patients diagnosed 2006-2017 were compared separately with regards to prevalent AITD to two groups: i) biopsy-free general population matched on birth year, sex

and county of residence at index year; and ii) biopsy-free full siblings to account for unmeasured confounders from common genetic risk and early environmental factors. Odds ratios (ORs) and 95% confidence intervals (CIs) were estimated via conditional logistic models stratifying on the matching variables or family groups and adjusting for education attainment, birth country, and history of celiac disease, inflammatory bowel disease, asthma, rheumatoid arthritis, psoriasis and type 1 diabetes. Sex difference in the association was tested via an “exposure × sex” interaction term. Separate analyses on MC subtypes and a sensitivity analysis of MC cases with at least 1-year follow-up before the index date (to minimize surveillance bias) were also carried out.

Results: A total of 10,448 MC cases and 49,935 controls were identified 2006-2017, among whom 1205 (11.5%) and 3791 (7.6%) were exposed to AITD, respectively. Compared to controls, MC patients were more frequently affected by at least one of the six other autoimmune comorbidities (8.3% vs 3.3%). As shown in Table 1, MC associated significantly with prevalent AITD at an OR of 1.60 (95% CI: 1.49-1.72) after adjusting for all covariates. This association appeared non-differential between collagenous colitis and lymphocytic colitis, and between males and females ($P_{\text{interaction}}=0.4$ for MC). When full siblings were compared to, the OR for MC association with AITD attenuated but remained statistically significant (OR: 1.22; 95% CI: 1.08-1.39). Sensitivity analyses also supported our main results.

	Population comparison			Sibling comparison
	MC	CC	LC	MC
Model 1	1.60 (1.49, 1.72)	1.63 (1.45, 1.84)	1.58 (1.45, 1.73)	1.64 (1.45, 1.85)
Model 2	1.60 (1.49, 1.72)	1.62 (1.43, 1.83)	1.59 (1.46, 1.74)	1.22 (1.08, 1.39)

Model 1 adjusted for only the matched or family group as stratum.

Model 2 further adjusted for birth country and education attainment in population analysis, and age, sex, index year as well as birth country and education attainment in sibling analysis, plus history of six autoimmune comorbidities in both analyses.

Abbreviations: CC, collagenous colitis; LC, lymphocytic colitis; MC, microscopic colitis.

Table 1. Odds ratios for the AITD-MC association.

Conclusion: Our findings corroborate the known association between MC and AITD and also support the notion that MC patients to a larger extent exhibit a predisposition towards autoimmune conditions. Our findings underscore the importance of investigating the underlying mechanisms of this association and emphasize the need for clinicians to consider MC in AITD patients presenting with diarrhoea.

Introduction: Enteric pathogens are a leading cause of diarrhea worldwide, even in high-income countries [1]. Moreover, patients with inflammatory bowel disease (IBD) are at an increased risk of infection [2,3] and gastrointestinal (GI) bacterial infections are commonly implicated as precipitants of IBD flares [4]. The diagnostic work-up therefore requires consideration of a wide variety of inflammatory or infectious diseases that mimic IBD.

Aims & Methods: Firstly, we aimed to evaluate in IBD patients factors that predispose to GI, secondly, factors that affect the severity of the GI infections and lead to hospitalization, and thirdly, how GI bacterial infections alter the activity of IBD further on.

This retrospective, observational, single-center, cohort study comprises 123 patients with ulcerative colitis (UC) or Crohn's disease (CD) with confirmed *Campylobacter* spp., *Yersinia* spp., *Salmonella* spp. or enterohemorrhagic *E. coli* (EHEC) infection, and their age and sex matched controls with IBD but without bacterial GI infection. We identified IBD patients with positive stool samples by performing a search combining the positive stool sample registry of the Hospital district of Helsinki and Uusimaa and the IBD registry of Helsinki University Hospital. Patient data from 1 January 2008 to 30 June 2023 was collected retrospectively from patient electronic charts.

Background factors, such as age, sex, IBD type and phenotype, previous surgical treatment, ongoing medication, previous IBD clinical activity, other comorbidities (based on Charlson Comorbidity Index [CCI]), smoking status, previous long-distance travelling, infectious symptoms, and need of medical consultations due to GI bacterial infection were evaluated. Follow-up data one to six months after the GI infection was analyzed. The results of the GI infection patients were compared with the controls.

Results: Out of 5194 IBD patients in the IBD registry, 123 patients were confirmed with *Campylobacter* spp., *Yersinia* spp., *Salmonella* spp. or EHEC infection. Of those with a GI bacterial infection, 64% (n=79) had UC and 36% (n=44) had CD. Patients with a GI bacterial infection diagnosis were more likely to have a flare and medication intensification in one to six months after the infection compared to the control group (37% vs 11%, p<0.001, and 37% vs 20%, p=0.006, respectively). Neither age, IBD phenotype, disease activity, CCI, IBD medication nor previous long-distance travelling to a lower hygiene country increased the risk of severe bacterial infection or the need hospital care.

Conclusion: IBD patients having GI bacterial infections are at a higher risk of experiencing an IBD flare and requiring an intensification in their IBD medication within one to six months after the infection. However, there is no significant association between different IBD medications or previous symptomatic IBD and the risk for hospitalization.

Introduction: We lack reliable biomarkers to identify patients with inflammatory bowel disease (IBD) at a greater risk of severe disease course. With emerging evidence that early step-down treatment in severe patients leads to better disease outcomes, alongside worries about overtreatment of mild patients, there is a clinical need to identify such biomarkers.

Aims & Methods: In this study, we explore genetic variants associated with severe disease course for ulcerative colitis (UC) in a nationwide cohort of 4491 patients from Denmark. We genotyped 4491 patients with UC (4153 from Danish birth blood spot archive; 338 from NorDIBD regional cohort), linking them with registry data capturing medical interactions throughout patients’ lifetimes. Patients who required 2+ IBD-related hospitalizations, 2+ IBD-related major surgeries, 1 IBD-related hospitalization and 1 IBD-related major surgery or use of systemic corticosteroids (≥5000 mg) in the first 3 years of diagnosis were defined as severe. We conducted a genome-wide association study comparing severe patients (N=1203) to those with a less severe disease course (N=3288).

Results: The GWAS identified a signal within the HLA region, with the HLA-DRB1*01:03 allele driving the association (OR=3.30 [2.23-4.87], P=2.08×10⁻⁹, UC carriage rate=2.8%). We did not observe an association with CD severity in a similarly ascertained cohort of 3688 individuals (P=0.79). Remarkably, carriage of DRB1*01:03 was associated with a seven-fold increase of major surgery risk (OR=7.05 [4.55-10.91], P=2.31×10⁻¹⁶) (Table 1). At the point of diagnosis, carriage of DRB1*01:03 was associated with higher CRP levels (β=2.68, P=1.70×10⁻⁷), f-cal levels (β=1.92, P=4.42×10⁻³) and a higher rate of hospitalization at diagnosis (OR=1.64, P=0.014), suggesting that the effect on severity is not limited to disease progression.

Outcome	N	OR [95% CI]	P-value
Main analysis	1203 vs. 3288	3.30 [2.23 - 4.87]	2.08E-09
≥5000 mg corticosteroids	821 vs. 3288	2.29 [1.42 - 3.69]	1.06E-03
≥2 hospitalizations	692 vs. 3288	5.16 [3.44 - 7.73]	1.72E-14
≥2 hospitalizations without major surgery	555 vs. 3288	5.93 [3.71 - 9.49]	2.28E-12
≥2 major surgeries	242 vs. 3288	7.24 [4.35 - 12.04]	1.49E-12
Major surgery	358 vs. 3266	7.05 [4.55 - 10.91]	2.31E-16
Intestinal resection	210 vs. 3266	7.42 [4.46 - 12.32]	2.33E-12
Enterostomy	151 vs. 3266	8.38 [4.67 - 15.03]	1.54E-10
Colectomy	338 vs. 3266	7.34 [4.73 - 11.40]	8.23E-17

Table 1: HLA-DRB1*01:03 has a consistent direction of effect and magnitude across different conditions that define patient severity; it is associated with multifaceted patient severity, rather than one particular factor entirely driving the association.

Conclusion: In this large-scale, unselected nationwide cohort study, we find that HLA-DRB1*01:03 is a biomarker of UC disease course that is associated with a more severe presentation at diagnosis, as well as higher subsequent risk of surgery and hospitalization. Demonstrating the association at a genome-wide significance level for the first time, this study revitalizes findings from smaller studies at the beginning of the genetic era which explicitly recruited severe patients and made estimating carriage effects difficult. While HLA-DRB1*01:03 is a low-frequency allele, patients who carry it are at a much higher risk of severe UC. As the cost of typing a single HLA allele is low (under 50 EUR) and several pharmacogenetic variants are beginning to be tested at diagnosis, we argue that it is a valuable addition to the arsenal of personalized healthcare tools.

Introduction: The true effect of having inflammatory bowel disease (IBD) in the development of infections has not been studied in depth since cohort studies are scarce and the results of studies are sometimes contradictory. Especially, this complication has not been addressed prospectively in an incident cohort of patients with IBD.

Aims & Methods: Aims: To assess, regarding infections in IBD: 1) incidence and type, 2) risk factors, 3) effect of type and the duration of IBD treatment, 4) impact in mortality 5) effect of IBD activity.

Methods: The INFEII registry (ClinicalTrials.gov: NCT02904590) is a prospective study promoted by GETECCU to determine the incidence and risk factors of infection in an inception cohort of patients with IBD and follow-up of at least 5 years. This longitudinal prospective study within the ENEIDA registry included incident cases with IBD. Patients were recruited between 2016 and 2020 with a planned follow-up of 5 years. All infections were detailed analysed. An infection was considered relevant when: 1) required hospital admission, 2) led to death or endangered the patient's life, 3) was treated with specific antibiotics, 4) occurred recurrently, and/or 5) required change/withdrawal of immunosuppressive treatment.

Results: The INFEII registry recruited 1456 patients from 28 centres throughout Spain. The median follow-up was 71 months (IQR 60-79 months). The description of the cohort is presented in Table 1. Of the 1456 patients, 580 (40%) presented at least one relevant infection. In total, 1321 infections were collected. One-hundred and seven infections (8%) required hospitalisation and four patients died (0.3%) over infection. Ninety-nine patients were lost to follow-up (22 died and 34 changed hospitals). The most prevalent infections were: ear-nose-throat in 238 cases, urinary tract infections in 237, respiratory in 234, COVID-19 in 133, skin infections in 127, dental in 64 and colitis/enteritis in 64. From the whole cohort and at some point, in time, 756 (52%) patients received 5ASA, 481 (33%) steroids (369 (25%) oral, 112 (7.7%) intravenous), 568 (39%) azathioprine, 72 (4.9%) methotrexate, 21 (1.4%) tofacitinib, 533 (37%) antiTNF, 141 (9.9%) ustekinumab and 77 (5.3%) vedolizumab. The effect of treatment and IBD activity in each infection is being analysed.

Variable (N%)	Total 1456	No infections 876	Any Infection 580	Univariate P
Gender (female)	668 (46)	378 (43)	290 (50)	0.01
Active smokers	314 (22)	177 (20)	137 (24)	0.09
Age at IBD diagnosis				
Mean (IQR)	42 (29-55)	42 (29-54)	41 (28-56)	0.74
>50 years	529 (36)	319 (36)	210 (36)	0.93
Unclassified colitis	27 (1.85)	20 (2.28)	7 (1.2)	0.14
Ulcerative colitis	781 (54)	484 (55)	297 (51)	0.14
Crohn's disease				
L1	648 (45)	372 (42)	276 (48)	
L2	280 (43)	153 (41)	127 (46)	
L3	122 (19)	77 (21)	45 (16)

	121 (19)	58 (16)	63 (23)	
Crohn's behaviour				
B1	486 (75)	284 (76)	202 (73)	0.34
B2	109 (17)	61 (16)	48 (17)	0.32
B3	61 (9)	33 (8.9)	28 (10)	0.32
perianal	123 (20)	65 (17)	58 (21)	0.28
History of severe infections (before IBD diagnosis)	36 (2.5)	13 (1.5)	23 (3.96)	0.004
Occupational risk	450 (31)	252 (29)	198 (34)	0.03
Comorbidity	256 (18)	143 (16)	113 (19)	0.12
Death (all causes)	22 (1.5)	11 (1.3)	11 (1.9)	0.33

Table 1. Clinical characteristics of patients included in the INFEII study.

Conclusion: Infections are frequent complications in patients with IBD, presented in 40% of them. Being a woman, having a history of past serious infections or occupational risk may be associated with infection

occurrence. It has to be determined if IBD activity and treatment pose a greater risk for infections. This paradigmatic study implies the first use of the ENEIDA registry in prospective research.

Disclosure: Nothing to disclose.

Introduction: IBD is a global health problem. It is necessary to understand the evolution and treatment exposure in a cohort of newly diagnosed IBD patients in the biologic era in the South of Europe

Aims & Methods: Aims: 1) To describe the main epidemiological and clinical characteristics of patients at IBD diagnosis and the long-term outcomes; 2) to analyse the use of drugs for IBD, and the need of hospitalisations and surgeries; 3) to compare IBD management based on the type of disease and the resources of the hospitals.

Methods: Prospective, population-based nationwide registry. Adult patients diagnosed with IBD —Crohn's disease (CD), ulcerative colitis (UC) or IBD unclassified— during 2017 in the 17 Spanish regions were included. Patients who consented were followed-up for 5 years (yr) after diagnosis. Treatment was grouped into 5 categories: mesalamine (oral or topical), steroids (intravenous, oral, or topical), immunomodulators (thiopurines, methotrexate or cyclosporine), biologics (anti-TNF, vedolizumab, ustekinumab) or JAK inhibitors (JAKi), and surgery. Hospitals were classified into high resources and low resources ones. Cumulative incidence of exposure to each of the studied treatments was estimated by Kaplan-Meier curves; curves were compared with log-rank test.

Results: A total of 3,301 incident cases of IBD diagnosed during 2017 in 108 hospitals, covering over 22 million inhabitants in Spain (about 50% of the population), were enrolled into the follow-up study. Main character-

istics of the cohort are summarised in table 1A and 1B. Median diagnosis delayed was 3.5 months (5.6 in CD and 2.7 in UC, $p<0.001$). During the 5-yr follow-up, 25% of UC patients progressed to more extensive involvement, while 8% of CD patients with inflammatory behaviour progressed to either stricturing or fistulising behaviour. Most of the patients who received mesalamine, corticosteroids, or immunomodulators initiated treatment within the first 2 years after diagnosis (figure 1). However, the cumulative incidence of biologics/JAKi usage steadily increased over time, reaching 49% by the 5-yr timepoint in CD. In terms of surgeries, a progressive increase in cumulative incidence was observed in CD; however, the incidence of colectomy remained stable in UC from the 2nd year post-diagnosis. The management and progression of IBD unclassified were similar to that of UC. Regarding the type of hospital, a higher cumulative incidence of biologics/JAKi usage, hospitalisations, and surgeries was observed in CD at high resources hospitals. No differences were observed in the use of other therapeutic resources or the management of UC.

	CD (N=1,526)	UC (N=1,633)	P-value
Median age at diagnosis, IQR (years)	40.9 (28.4-54.4)	45.6 (34.5-57.1)	<0.001
Median diagnosis delay, IQR (months)	5.6 (1.8 - 15.2)	2.7 (1.3 - 5.8)	<0.001
Male sex, n (%)	766 (50.2)	897 (54.9)	0.008
Symptoms at diagnosis, n (%)	13,61 (89.2)	15,38 (94.7)	<0.001
Family history, n (%)	272 (17.8)	214 (13.1)	<0.001
Extraintestinal manifestations, n (%)	294 (19.3)	157 (9.6)	<0.001
Former smoker, n (%)	364 (23.9)	765 (46.8)	<0.001
Mesalazine, n (%)	665 (43.6)	1,582 (96.9)	<0.001
Steroids, n (%)	1,205 (79.0)	843 (51.6)	<0.001
Immunomodulators, n (%)	878 (57.5)	309 (18.9)	<0.001
Biologics/JAK inhibitors, n (%)	675 (44.2)	281 (17.2)	<0.001
Hospitalisations, n (%)	657 (43.1)	430 (26.3)	<0.001
Surgery, n (%)	247 (16.2)	40 (2.5)	<0.001

Continuous variables are reported as median (p25-p75), and the number of non-missing values is provided. Categorical variables are reported as number of occurrences in each category. Percentages were calculated with the total sample as denominator, except subcategories of types of EII. P-values are calculated performing U Mann-Whitney tests for continuous variables and Pearson's χ^2 tests for categorical variables. IQR, interquartile range.

Conclusion: In the EpidemIBD large-scale epidemiological study, we have observed that the delay in diagnosing IBD is shorter than previously described. Approximately 50% of patients with CD and 20% of patients with UC end up receiving biologics/JAKi in the first 5 yrs following diagnosis. The percentage of patients undergoing surgery was lower than previously reported; in the case of UC, the majority of colectomies occurred within the first 2 yrs after diagnosis.

Introduction: There is a well-known association between inflammatory bowel disease (IBD) and primary sclerosing cholangitis (PSC). It is estimated that approximately 2% of IBD patients have PSC. However, there is little data regarding the impact of PSC on the prognosis of patients with IBD.

Aims & Methods: We conducted a retrospective cohort study using TriNetX, a multi-institutional database, to compare outcomes of patients with IBD and those with both IBD and concomitant PSC between 2003 and 2023. All patients with a confirmed diagnosis of Crohn's disease (CD), ulcerative colitis (UC), or indeterminate colitis with or without PSC were eligible. One-to-one propensity score matching was employed to balance demographic parameters, comorbid conditions, and IBD medications between cohort 1 (IBD) and cohort 2 (IBD and concomitant PSC). The primary endpoint was a composite endpoint including risk of mortality, hospitalization, and surgery. Secondary endpoints were the risk of mortality, IBD-related surgery, and IBD-related hospitalization. Risks were expressed as Hazard Ratio (HR) with a 95% confidence interval (CI).

Results: A total of 409,104 IBD patients were analyzed, including cohort 1 (405,923) and cohort 2 (3,181). After propensity score matching, 3007 patients from each group were included (mean age 48.1 ± 19.4 years, female 40%, UC 75%, CD 24,8%). Cohort 2 patients had an higher risk of experiencing the composite endpoint compared to cohort 1 group (HR 1.326, CI 1.232-1.428). Similarly, a higher risk of experiencing hospitalization and mortality was identified in subjects with IBD and concomitant PSC (HR 1.326, CI 1.224-1.436 and HR 1.697, CI 1.467-1.963 respectively). No difference was detected in terms of surgery between the two groups (HR 1.181, CI 0.970-1.438). Another analysis was performed to compare the outcomes of patients with CD or UC with or without concomitant PSC. Both CD and UC patients with concomitant PSC had an higher risk of achieving the composite endpoint (HR 1.186, CI 1.026-1.372 and HR 1.293, CI 1.189-1.408, respectively). An increased risk of mortality and hospitalization was found both in patients with CD (HR 2.164, CI 1.587-2.952, and 1.207, CI 1.031-1.412, respectively) and UC (HR 1.875, CI 1.578-2.228 and HR 1.279, CI 1.168-1.401, respectively) and concomitant PSC. In patients with CD or UC and concomitant PSC no increased risk of surgery was found (HR 0.954, CI 0.641-1.421 and HR 1.102, CI 0.886-1.369, respectively).

Conclusion: In the largest case series of patients with IBD and PSC, concomitant PSC increased risk of mortality and IBD-related hospitalization.

Disclosure: Nothing to disclose.

DIAGNOSIS OF INFLAMMATORY BOWEL DISEASE DO NOT IMPACT GLP-1 ANALOGS EFFICACY: AN OBSERVATION FROM THE EPI-IIRN

Introduction: There is a global increase in the metabolic syndrome and inflammatory bowel diseases (IBD) prevalence, with a rise in patients who are being treated for both syndromes[1]. The growing use of GLP-1 analogs for both diabetes mellitus type 2 (DM2) and weight loss and the fact that these are originally gut-derived hormones with many gastrointestinal (GI) functions have raised concerns related to GLP-1 treatment in patients with IBD. We aimed to examine the efficacy of these agents in an Israeli nationwide cohort of IBD patients and matched controls (epi-IIRN).

Aims & Methods: IBD patients were identified using a previously validated algorithm and non-IBD matched controls (1:2-3 ratio) by year of birth, sex and jurisdiction. DM2 patients were identified if they had at least two occurrences of either any of the DM2 international classification of diseases 9 diagnoses, or a purchase of a non-insulin anti-diabetic medication. We included patients with GLP-1 dispensation for more than 6 months. The outcomes were changes in glycated hemoglobin (HbA1c) and body mass index (BMI), compared using Mann-Whitney test. Linear mixed effects models were constructed, with patients as random effects and change in either HbA1c or BMI (in each model) as outcomes. The models [HB1] were adjusted for sex, age, baseline HbA1c value, insulin and SGLT-2i treatment. Missing numeric values were carried forward from a previously recorded value for the same patient.

Results: Out of 1426 patients with diabetes who initiated GLP-1 agonists, 861 were treated for at least 6 months, 437 with IBD and 424 controls. IBD patients were significantly older, had lower BMI (<1 point difference), and were more likely to use glucocorticoids (Table 1). The change in HbA1c was not significantly different between IBD patients and controls (-0.3 [-1.1, 0.1] and -0.4 [-1.1, 0.1], respectively, p=0.74), neither was the change in BMI (-0.4 [-1.9, 0.5] and -0.5 [-2.3, 0.1], respectively, p=0.14). In the multivariate mixed effects models, IBD status in GLP-1 agonist users were not associated to change in HbA1c or change in BMI during treatment.

	IBD (n=437)	Non IBD (n=424)	P value
Follow up time, years	2.5 [1.3, 5.5]	2.8 [1.4, 6.0]	0.35
Age, years	61.4 [52.4, 67.6]	58.4 [50.2, 65.5]	<0.01
Male, n (%)	224 (51.3)	196 (46.2)	0.16
BMI	32.3 [29.8, 36.0]	33.5 [30.7, 37.6]	<0.01
HbA1c (baseline %)	7.9 [7.3, 8.8]	8.0 [7.3, 8.9]	0.93
Albumin, g/dL	4.2 [3.9, 4.3]	4.2 [4.0, 4.4]	0.6
Insulin	184 (42.1)	153 (36.1)	0.08
SGLT-2i	96 (22.0)	80 (18.9)	0.30
Glucocorticoids use	27 (6.2)	12 (2.8)	0.03

*data is presented as median [IQR] or n (%)

Conclusion: GLP-1 analogs show similar efficacy in patients with DM2 and IBD compared with patients without IBD. Further evidence is needed for their efficacy and tolerability in patients with IBD and overweight.

HIGH-RESOLUTION RECTOSCOPY USING DUAL-MODE MHZ OPTICAL COHERENCE TOMOGRAPHY - A STEP TOWARDS REAL TIME 3D ENDOSCOPY

Introduction: In addition to colonoscopy and histology, endoscopic ultrasound (EUS) plays a pivotal role in assessing rectal cancer (T-staging). As new therapeutic options emerge, exact imaging of the tumor is essential for the primary diagnosis and the evaluation of therapeutic response. In this regard, optical coherence tomography (OCT) offers a superior axial and lateral resolution compared to conventional rectal EUS and may contribute to individualized therapeutic strategies.

Aims & Methods: Our study aimed to evaluate the imaging quality of our further refined OCT-rectoscope prototype, which integrates an extended range additional to the optimized standard mode.

We integrated a double ferrule design with a fiber optical switch into a MHz-OCT rectoscope.

The performance of this adjustable OCT-rectoscope was assessed in two human colons, post-mortem and *in situ*. The body donors were preserved using an ethanol-glycerol-lysoformin-based technique resulting in true-to-life tissue consistency.

Results: The extended range mode adjusted the focus depth and imaging range and ensured imaging quality despite varying colon diameters or altered total wall thickness. The optimized standard mode gave a detailed resolution of the different rectal wall layers. Compared to the former prototype MHz-OCT rectoscope and rectal EUS, the images stood out: The mucosa appeared as a broad pale gray band, exactly circumscribed by the lamina muscularis mucosae. The submucosa was visualized as an inhomogeneous, light gray broad area. Furthermore, the muscularis propria comprising the circular and longitudinal muscle layer manifested as two homogeneous dark gray bands. The serosa was displayed as a bright band.

Conclusion: The new dual-mode MHz-OCT design allows a fast change between the extended range and the optimized standard mode. The imaging quality in both modes was exceptional compared to the state of the art EUS, with clear delineation of the different rectal wall layers, providing ideal conditions for accurate staging of rectal cancer. Further imaging studies are warranted to evaluate this dual-mode MHz-OCT rectoscope in human colons *in vivo*. In the future, this technique could serve additionally in indications like inflammatory bowel disease to quantify inflammation more precisely. Moreover, it could be integrated into a colonoscope design to evaluate the whole colon.

ERIC, NEW VIRTUAL ASSISTANT FOR COLONOSCOPY: A PILOT STUDY

L.E. Del Vecchio¹, S. Pecere¹, F. Barbaro¹, L.G. Papparella¹, C. Spada¹

¹Catholic University of Rome, Gemelli Hospital, Gastroenterology and Digestive Endoscopy Unit, Roma, Italy

Contact E-Mail Address: livioenricodelvecchio@gmail.com

Introduction: A successful colonoscopy requires ideal stool preparation, yet the percentage of insufficient bowel preparation is still very high. Frequently, the patients use website information on colonoscopy preparation. Conversely, the daily activity of the hospital staff consists of spending time with patients, communicating with them and giving answers to a high number of questions coming from patients regarding the preparation for the procedure or the exam itself. Hence, the idea to adopt a rapid and intuitive patient-oriented digital service to respond to their needs, the virtual assistant Eric.

Aims & Methods: Endo-Chat is an automated online communication platform, powered by AI (Artificial Intelligence) with the use of the Natural Language Processing and Deep Learning technologies, that answers procedure-related questions in real-time. The engine is named ERIC, stands for "Endoscopy Robot for Intelligent Chat" and is an intelligent chatbot, capable of answering autonomously to most of the doubts of a patient who is supposed to undergo an endoscopic examination.

Results: Since the introduction of the conversational artificial intelligence system at the Policlinico Gemelli starting from 24th of January 2022 to the 16th of March 2023, Eric has been able to autonomously manage 94% of the questions sent by patients, thus forwarding only the remaining 6% (of the requests) to specialized human operators.

We calculated that in the pre-pilot phase, a large part of the daily activity of nurses was dedicated to communicating with patients, around 40 hours per week, while in the post-pilot phase, the time spent for communication was significantly reduced to 15 hours per week. According to OECD Health Statistics 2022, the average annual salary of a European nurse is 35,300 euros, with an annual hypothetical saving of 22,062 euros, comparable to a part-time contract.

Also, the number of cancelled procedures for poor patient preparation has fallen from 22 to 7 per week, considering a volume of 200 procedures per week.

Regarding patient's experience, users can leave voluntary feedback on their virtual assistant experience directly on the ERIC website, evaluating the quality of the service. Patient service evaluations were enthusiastic till now, as 63% rated the service as excellent.

Conclusion: In our observational pilot study, the first in Europe to our knowledge, we assessed the benefits measurement for patients and Hospital staff. Starting from these preliminary interesting results, we can speculate that the introduction of Endo-Chat in high-volume endoscopy service is feasible and useful not only for patients but also for hospital staff.

PREVALENCE OF COLONOSCOPY-RELATED ADVERSE EVENTS IN OLDER ADULTS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Q. Lu¹, X.-H. Lv¹, J.-L. Yang¹
¹West China Hospital of Sichuan University, Department of Gastroenterology and Hepatology, Chengdu, China

Contact E-Mail Address: 237199636@qq.com

Introduction: The need for colonoscopies in the elderly has significantly grown compared to 20 years ago. Furthermore, the issue of advanced age has long been a concern to colonoscopists. Our study aimed to evaluate the occurrence of colonoscopy-related adverse events (AEs) in older individuals.

Aims & Methods: A detailed search was conducted on October 28th, 2023, using the Pubmed, Embase, and Cochrane Library databases. Meta-analyses were performed using the generalized linear mixed model and the results were expressed for pooled rate along with relevant 95% confidence intervals (CIs).

Results: We retrieved 14748 records, of which 34 studies were included. The overall pooled rate of colonoscopy-related perforation, bleeding and death in the elderly were 0.072% (95% CI 0.051-0.102; I²=82%), 0.184% (95% CI 0.093-0.364; I²=99%), and 0.026% (95% CI 0.002-0.431; I²=0%), respectively. Patients aged over 80 years had a 2.44-fold (RR 2.44; 95% CI 1.15-5.66; I²=79%) risk of perforation and 1.24-fold (RR 1.24 95% CI 1.04-1.49; I²=0%) risk of bleeding comparing with patients aged 80 years and under. For screening purposes, the pooled rate of perforation and bleeding were 0.086% (95% CI 0.071-0.103; I²=0%) and 0.170% (95%CI 0.049-0.591; I²=96%), respectively. The rates were 0.076% (95% CI 0.029-0.202; I²=0%) and 0.166% (95% CI 0.062-0.438; I²=54%) for diagnostic purposes, respectively. In comparison to non-therapeutic colonoscopies, therapeutic colonoscopies showed a higher rate of perforation (0.044% vs. 0.004%) and bleeding (0.167% vs. 0.004%).

Conclusion: We reported on the prevalence of colonoscopy-related AEs in older adults, emphasizing concerns over the safety of colonoscopy for those aged over 80 years.

Introduction: There is a steadily increasing interest among patients in obtaining medical information from electronic sources. ChatGPT, a conversational agent utilizing artificial intelligence, has been demonstrated as a reliable source of information for patients before a colonoscopy (1) as well as in various medical purposes.

Aims & Methods: The aim of this study is to determine the ability of ChatGPT 3.5 to issue recommendations after a screening colonoscopy for colorectal cancer. This is a single-center observational cross-sectional study conducted in 2023. Only colonoscopies for screening purposes were included. Colonoscopies performed for gastrointestinal bleeding, follow-up of chronic inflammatory bowel diseases, post-operative follow-up of colorectal cancer, or in patients under 40 years old were excluded. Colonoscopy reports and corresponding pathology reports were entered into a conversation with ChatGPT 3.5. The colonoscopy report includes the quality of colonic preparation, withdrawal time, results, and specimens sent

for histology. ChatGPT 3.5 was asked to determine the time interval for the follow-up colonoscopy using the Consensus of the American multisociety taskforce of 2020 (2). The answers from ChatGPT were compared to the recommendations, and were validated by two gastroenterologists. The answers were categorized as “correct”, “underestimated” if the interval recommended by ChatGPT is shorter than the one provided by the consensus, and “overestimated” if the interval recommended by ChatGPT is longer than the one provided by the consensus.

Results: A total of 1259 colonoscopies were considered for analysis. The average age at the time of colonoscopy was 61.6 ± 11.0 years old. Among the participants, 688 (54.6%) were women and 517 (45.4%) were men. ChatGPT® issued a correct recommendation in 892 cases (70.8%). The surveillance interval was underestimated in 260 (20.7%) cases and overestimated in 107 (8.5%) cases.

The accuracy of the recommendations for each identified category is represented in the table below.

Result	Correct answer N (%)	Incorrect, under- estimate interval N (%)	Incorrect, overestimate interval N (%)
Normal colonoscopy with adequate bowel preparation (n= 590)	544 (92.2%)	46 (11.8%)	0 (0%)
Inadequate bowel preparation (n= 190)	100 (52.6%)	0 (0%)	90 (47.4%)
1-2 tubular adenomas with low grade dysplasia (n= 180)	26 (14.4%)	154 (85.6%)	0 (0%)
3-4 tubular adenomas with low grade dysplasia OR hyperplastic polyp ≥ 1cm (n=58)	53 (91.4%)	3 (5.2%)	2 (3.4%)
Polyp with high grade dysplasie, with villous component, OR serrated with dysplasia or ≥ 1cm, OR 5 or more adenomas (n=121)	108 (89.3%)	7 (5.8%)	6 (4.9%)
Serrated polyp without dysplasia AND < 1cm (n=5)	5 (100%)	0 (0%)	0 (0%)
Polyp ≥2cm resected with piecemeal mucosectomy (n=7)	6 (85.7%)	0 (0%)	1 (14.3%)
Ten or more adenomas (n=8)	4 (50%)	0 (0%)	4 (50%)
Total (n=1259)	892 (70.8%)	260 (20.7%)	107 (8.5%)

Table 1. Accuracy of the recommendations issued by ChatGPT 3.5 according to the colonoscopy result.

Conclusion: ChatGPT appears to be a reliable tool for issuing recommendations after a screening colonoscopy. It is limited by the recognition of poor preparation requiring closer surveillance. Artificial intelligence could be exploited and integrated into colorectal cancer screening programs. It could also be used by a patient to remind them of their next colonoscopy, except in cases of poor colonic preparation.

Contact E-Mail Address: stepan.suchanek@uvn.cz

Introduction: The colorectal cancer (CRC) incidence and mortality might be influenced by the screening and diagnostic methods related to the pre-cancerous lesion (adenomatous polyps) and colorectal neoplasia identification. In the Czech Republic, there are two methods available. First is the annual (in age 50–54) or biennial (in age over 50) immunochemical fecal occult blood test (FIT), followed by FIT+ colonoscopy, if positive. The second one is screening colonoscopy (in age over 50) which might be repeated in 10 years interval. Besides these screening methods, diagnostic FIT and colonoscopy are available for symptomatic patients.

Aims & Methods: Evaluation of the CRC incidence and mortality trends between years 2000 (introduction of the screening program) and 2021 (most recent data available) and target population coverage (three years interval) by screening and diagnostic FIT and colonoscopy (CRC-affecting methods) in last 10 years (2012–2022). The analysis was performed using the National Registry of Reimbursed Health Services in the Czech Republic (data since 2010) and the Registry of Preventive Colonoscopies (data since 2006).

Results: In years 2000–2021, the decrease in CRC incidence and mortality by 31.6% and 46.3%, respectively, was noticed. Target population (individuals age over 50) coverage of all CRC-affecting methods have risen in years 2012–2022 from 43.0% to 47.8%. In year 2022, the target population consists of 4,140,725 individuals and screening FITs were performed in 1,490,661 persons (36.0%), screening colonoscopies in 109,200 individuals (2.6%), diagnostic FITs in 97,505 patients (2.4%) and diagnostic colonoscopies in 283,462 patients (6.8%). In years 2006–2022, 474,063 preventive colonoscopies were done, adenomas were removed in 179,478 patients (37.9%) and colorectal cancers were diagnosed in 13,428 patients (2.8%) (48.8% of them in stage I).

Conclusion: The indirect evidence shows the probable impact of the high numbers of the screening and diagnostic fecal immunochemical tests and colonoscopies performed, adenomas removed, and early-stage cancers diagnosed on the continuous decrease of the colorectal cancer incidence and mortality in the Czech Republic.

VARIATIONS IN USE OF FAECAL IMMUNOCHEMICAL TESTING (FIT) IN PRIMARY CARE IN ENGLAND: A POPULATION-BASED COHORT

A. Morton^{1,2}, C. Crooks^{1,2,3}, J. West^{1,2,3}, B.D. Nicholson⁴, D.J. Humes^{1,2,3}

¹University of Nottingham, Nottingham, United Kingdom, ²NIHR Nottingham Biomedical Research Centre, University of Nottingham and Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom, ³Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom, ⁴Nuffield Department of Primary Care Health Sciences, University of Oxford, Oxford, United Kingdom

Contact E-Mail Address: alastair.morton1@nottingham.ac.uk

Introduction: The United Kingdom National Institute for Health and Care Excellence recommends Faecal Immunochemical Testing (FIT) for all patients presenting to primary care with symptoms suggestive of colorectal cancer. How use of this test varies across England is unknown, which this study aimed to quantify.

Aims & Methods: Routinely-collected primary care records (Clinical Practice Research Datalink Aurum) were used to assess variations in symptomatic FIT use in adults (≥18 years) between regions and over time in England from 2019 to 2023. Rates were calculated using the population registered to each primary care practice as the denominator, with analysis split by calendar year.

The first coded FIT test with a numerical result per patient each year was extracted from the primary care records. Rates of testing were calculated using Poisson regression, adjusted for other confounders. Results were described between groups, regions and years at the recommended threshold of ≥10 µgHb/g faeces (results above this threshold henceforth referred to as FIT10), describing the proportions likely to have a secondary care referral based on national guidance. Logistic regression was used to compare the impact of year, region, gender and age on the differences in FIT10.

Results: Between 01/01/2019 and 05/06/2023 there were 531,735 FIT results among 495,121 patients and a denominator population of 17,910,681. The number of completed FITs increased from 8,395 in 2019 to 237,708 in 2022 (the last complete year within the study), with a corresponding ~thirty-fold increase from 0.69 tests per 1000 person-years in 2019 (95%CI 0.68–0.71) to 19.57 per thousand person-years in 2022 (95%CI 19.50–19.65). There was large variation in testing between regions, with rates 3.6 times higher in the North East compared to the West Midlands (17.05 per thousand person-years, 95%CI 16.87–17.23 versus 4.72 per thousand person-years, 95%CI 4.67–4.76). These differences persisted to 2022, with less than half the rate in the West Midlands (11.32) compared to the North East (31.85 per thousand person-years).

20.4% of results were FIT10. Despite increased testing, the overall proportion FIT10 did not change over time. 51.7% of all tests FIT10 were in those over 70 years of age. The percentage FIT10 was lower in regions with higher rates of FIT testing, for example FIT10 ranged from 16.7% in the South West (rate of testing 14.62 per thousand person-years) to 25.3% in the South East (rate of testing 8.00 per thousand person-years). After adjusting for year, region, gender and age, this difference persisted (adjusted OR 0.57, 95%CI 0.55–0.58) comparing FIT10 in the South West to the South East. The difference in proportions FIT10 between regions showed some convergence over time, from a range of 16.6%–26.7% (10.1%) in 2021 to 15.8%–23.7% (7.9%) in 2023.

Conclusion: There has been a marked increase over time in the use of FIT for patients with symptoms in primary care, with large and persistent variations between regions of England. The overall proportion FIT10 has not decreased over time with increasing use, however there were large

differences in FIT10 between regions that correlated with rates of testing. These regional differences persisted but reduced over time as testing rates increased nationally. It is likely that clinical pathway differences in the implementation of FIT over time and between regions explain the variations we have observed. If used as a guide to referral, such variation could lead to inequalities in colorectal investigation and diagnosis.

TESTING GERMLINE MUTATIONS PATIENTS WITH 10-19 LIFETIME COLORECTAL ADENOMAS: IS IT NECESSARY?

P.F. da Silva Mesquita², J. Rodrigues¹, C. Costa², M.M. Estevinho², T. Freitas², A. Ponte²

¹Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova de Gaia, Portugal, ²Gastroenterology, Porto, Portugal, ³CHVNG/E, Gastroenterology, Vila Nova De Gaia, Portugal

Contact E-Mail Address: pedro.filipe.silva.mesquita@gmail.com

Introduction: The prevalence of pathogenic APC and biallelic MUTYH mutations, in patients with 10 to 19 cumulative colorectal adenomas (CRA), is stated to be 5% and 4%, respectively. ESGE and NCCN suggest referring patients with ≥ 10 CRA to genetic counseling, limiting direct testing to patients with ≥ 20 CRA. USMSTF states that patients with multiple CRA should be considered for genetic testing. BSG recommends testing all patients under 60 years-of-age with ≥ 10 CRA, and over 60 only patients with family history of colorectal cancer (FHC) or polyposis. Predictors are needed to further select patients and maximize the diagnostic yield.

Aims & Methods: To assess the prevalence and predictors of pathogenic APC and MUTHY mutations in patients with 10-19 lifetime adenomas to the date of the genetic test.

We retrospectively included all patients undergoing screening for APC and MUTYH mutations, in our center since 2010. Patients undergoing family screening or with a history of colorectal cancer (CRC) were excluded. Endoscopic, histological, and family history data was collected.

Results: 96 patients (36%) presented with 10-19 cumulative adenomas. Patients were on average 64,45 ($\pm 9,33$) years and 78.1% were male. FHC was present in 21,8%, diminishing to 19,7% when considering first-degree relatives only and to 4,2% applying ESGE familiar-CRC definition. On average patients had 5 advanced adenomas (size ≥ 10 mm, tubulovillous/villous histology or with high-grade dysplasia) and 66.7% had ≥ 10 CRA on a single colonoscopy. No patients were found to have pathogenic mutations of the APC and MUTYH genes.

Conclusion: Despite a combined expected prevalence of 7-12/100 patients, and the high presence of risk factors in our cohort, no pathogenic mutations were found. ESGE and NCCN criteria would have led to the referral of 96 patients to genetic counseling and BSG recommendations would trigger 42 genetic tests. We question the prevalence of these mutations in the Portuguese population and the cost-effectiveness of testing patients with 10-19 cumulative CRA.

Disclosure: Nothing to disclose.

Contact E-Mail Address: sophie.corneillie@azdelta.be

Introduction: Colorectal cancer (CRC) poses a significant global health threat, with high incidence rates and a major impact on public health. Despite screening and diagnostic advances, CRC claimed 2,520 lives in Belgium in 2021. Colonoscopy helps identify and remove polyps, reducing CRC risk. However, post-colonoscopy CRC (PCCRC) cases still occur, influenced by factors like inadequate bowel preparation and short withdrawal time. Understanding these factors is vital for enhancing CRC screening and prevention. Utilizing a POWERBI dashboard can aid in collecting data on screening colonoscopies, including key performance indicators like withdrawal time and adenoma detection ratio (ADR).

Aims & Methods: This study aimed to create a comprehensive dashboard for analyzing PCCRC at our center. Secondary goals included identifying factors contributing to PCCRC in our patient population. We designed an integrated dashboard and analyzed coded data from electronic patient records, including colonoscopy findings matched with histopathological data. A retrospective analysis identified patients with PCCRC and factors possibly contributing to its development. Each case underwent detailed manual review. Colonoscopy indications analyzed were positive iFOBt, surveillance and screening.

Results: The dashboard was developed by a data analyst under the guidance of the clinical nurse specialist in endoscopy and the gastroenterologists in our center. The initial version of this dashboard consisted of the following data: demographics and comorbidities of the patients, number of colonoscopies and their indications, adenoma detection ratio per endoscopist, histopathology data coupled with the data from the endoscopy report, BBPS and withdrawal time. Using diagrams, an easy overview of the current available data is readily visualised.

From the 13200 screening colonoscopies performed between June 2019 and april 2024, 274 (2.08%) CRC's were detected. 16/274 (5.84%) were PC-CRC (9 males and 7 females), including 1 patient with Lynch syndrome, 1 Crohn's disease, and 1 signet ring cell carcinoma. The detected carcinomas were located in the ascending colon (1), hepatic flexure (2), transverse colon (1), cecum (5), sigmoid (5) and rectum (2). The median time to the detection of a PCCRC was 23 months (range 5 - 38). The mean age of individuals diagnosed with PCCRC was 70 years (range 37 - 88). The median withdrawal time at the index colonoscopy was 8.5 minutes (range 3 - 54). The Boston Bowel Preparation Score (BBPS) was utilized to assess bowel preparation quality of the index colonoscopy, with a median score of 9 (range 3 - 9). The median ADR in our center is 46.2%. Three patients died of PCCRC.

Conclusion: We identified and analysed PCCRC and interval cancers by using a newly developed dashboard. This dashboard extracts real-time coded data from patient files and allows for retrospective, real-time and ongoing monitoring. By using this tool as an audit, healthcare providers can take targeted actions to improve the quality of colonoscopies and aim

to reduce the incidence of PCCRC. In the future, expansion of this dashboard should allow to extract data allowing for comparing groups and analyse risk factors associated with PCCRC and interval cancer. Ideally, a dashboard should be considered to be integrated in all endoscopy reporting systems providing real-time data on endoscopist's performance and patient outcomes.

Introduction: Colonoscopic surveillance reduces colorectal cancer (CRC) incidence and mortality in Lynch syndrome (LS) carriers. Still, its invasiveness and high costs highlight the need for a non-invasive approach to predict the presence of neoplastic lesions.

Aims & Methods: This study aimed to identify faecal bacterial biomarkers to discern between carriers with colorectal lesions and those with normal colon.

Two independent Spanish cohorts (a training and a validation cohort) were recruited through two multicenter studies (Table 1). Participants provided a faecal sample before surveillance colonoscopy to quantify the abundance of *F. prausnitzii* (FPRA) and its phylogroups I and II (PHGI and PHGII), *P. stomatis* (PTST), *B. fragilis* (BCTF), *B. thetaiotaomicron* (BCTT), B46 (best BLAST match *S. variabile*), *G. morbillorum* (GMLL), B48 (best

BLAST match *R. faecis*), and *E. coli* (ECO) through qPCR. Eubacteria (EUB) was quantified as the total bacterial load. Participants were classified based on colonoscopy findings as normal colonoscopy (NC), non-advanced adenoma (NAA), and advanced neoplasia (AN, including advanced adenoma and CRC). A bacterial signature for neoplasia prediction was defined and validated in the training and validation cohorts, respectively.

		Training cohort	Validation cohort
Age	mean (range)	51 (25-83)	47 (20-75)
Sex (female)	n (%)	32 (64.0)	75 (65.8)
Diagnosis	NC (%)	40 (80.0)	71 (64.5)
	NAA (%)	6 (12.0)	35 (31.8)
	AA (%)	3 (6.0)	3 (2.8)
	CRC (%)	1 (2.0)	1 (0.9)
Mutated gene	High penetrance	MLH1 (%) - MSH2 (%) - EPCAM (%)	18 (36.0) - 9 (18.0) - 0 (0.0)
	Low penetrance	MSH6 (%) - PMS2 (%)	37 (33.6) - 25 (22.9) - 1 (0.9)
Total		n	50
			110

Table 1. Main characteristics of the study participants. NC, normal colonoscopy; NAA, non-advanced adenoma; AA, advanced adenoma; CRC, colorectal cancer.

Results: The bacterial abundances were analysed in the training cohort according to age, sex, body mass index (BMI), germline mutation, and colonoscopy findings. Significant moderate positive correlations were identified between the abundances of BCTF and age ($r=0.325$, $p=0.040$), and PHGII and BMI ($r=0.399$, $p=0.010$). A significant negative correlation was identified between GMLL abundance and BMI ($r=-0.331$, $p=0.036$). Patients harbouring *MLH1* mutations exhibited a significantly higher abundance of FPRA compared to *PMS2* carriers ($p=0.048$). Patients with neoplasia (NAA+AN) presented significantly lower abundances of BCTF ($p=0.027$) and B48 ($p=0.038$) than patients with NC. Patients with AN presented a significantly lower abundance of PTST compared to patients with NC or NAA ($p=0.032$).

Although all the bacterial markers achieved a sensitivity of 100% to predict the presence of neoplasia, none of them presented a specificity higher than 25% by itself. To maintain sensitivity and increase specificity a bacterial signature was defined including ECO, BCTF, GMLL, FPRA, PHGI, PHGII, and B46 combined with the inherited mutation. The signature showed 100% sensitivity (SS), 52.50% specificity (SP), 34.48% positive predictive value (PPV), and 100% negative predictive value (NPV). This signature was subsequently validated demonstrating 100% SS, 56.45% SP, 53.44% PPV, and 100% NPV.

Conclusion: A new faecal bacterial signature to predict the presence of colorectal neoplasia in LS carriers has been identified, showcasing its potential usefulness to improve and personalise LS surveillance, optimising endoscopic resources, and providing a less invasive and cost-effective approach.

Contact E-Mail Address: miloskbcz18@gmail.com

Introduction: Although the exact mechanism of metabolic dysfunction-associated steatotic liver disease (MASLD) development is unknown, new research indicates that the gut microbiota may significantly impact the disease's progression through one of its most vital functions—the synthesis of butyrate. Animal models have already demonstrated the positive effects of butyrate administration, but no studies have yet investigated the possible impact of oral butyrate supplementation in the population of MASLD patients.

Aims & Methods: We conducted an interventional study of 177 individuals diagnosed with MASLD. MASLD was defined by a baseline attenuation coefficient (ATT) obtained by point shear-wave elastometry (pSWE) of 0.63 dB/cm/MHz or higher and a baseline alanine-aminotransferase (ALT) of more than 40 IU/L. After diagnosis was made, a total of 121 patients were administered 1000 mg of calcium butyrate, whereas 56 patients were treated with 1000 mg of sodium butyrate. Patients were prescribed a Mediterranean diet regimen, which required an intake of 20–30 kilocalories per kilogram of body weight, split between 35–40% fat, 20% protein, and 40–45% carbs. At the start of the investigation, patients were requested to provide stool samples for stool short chain fatty acids (SCFA) analysis and blood samples for miRNA panel (miR-192, miR-885, miR-122) analysis. We also followed the elastometry parameter, ALT, lipidogram, high-sensitive C-reactive protein (hsCRP), tumor necrosis factor- α (TNF- α), interleukin-1, interleukin-6, and cytokeratin-18 dynamics during the 12-week treatment period.

Results: We did not observe a significant effect of butyrate supplementation on the level of liver steatosis (baseline vs. endpoint ATT- 0.78 vs 0.76 dB/cm/MHz, $p=0.33$) and ALT (baseline vs. endpoint ALT 72 vs 73 IU/L, $p=0.58$). No significant effects were observed in inflammatory markers or lipidogram dynamics. Neither calcium- nor sodium-butyrate showed superiority. However, the benefit of butyrate supplementation was observed in the population of patients with MASLD and body mass index below 25 kg/m² (baseline vs. endpoint ATT 0.80 vs 0.77 dB/cm/MHz, $p=0.043$; baseline vs endpoint hsCRP 3.7 vs. 2.4 mg/L, $p<0.001$), baseline SCFAs below 20 μ mol/g (baseline vs. endpoint ALT 78 vs. 74 IU/L, $p=0.0142$; baseline vs. Endpoint ATT 0.84 vs. 0.78 dB/cm/MHz, $p=0.002$), baseline hsCRP levels above 10 mg/L (baseline vs. endpoint hsCRP 14.6 $\pm$ 3 vs. 6.4 $\pm$ 1.4 mg/L, $p<0.001$) and patients with upregulated miR-192 (baseline vs endpoint TNF α 30.4 vs. 24.6 pg/ml; baseline vs. endpoint cytokeratin-18 229 vs. 211 IU/L, $p=0.025$).

Conclusion: Oral butyrate supplementation could benefit selected groups of patients with MASLD, especially in lean, those with higher inflammatory status, or low stool SCFAs.

Disclosure: Nothing to disclose.

Introduction: In the absence of any globally approved pharmacotherapy, current guidelines recommend lifestyle modification and weight loss in people with obesity and metabolic dysfunction-associated steatotic liver disease (MASLD), including metabolic dysfunction-associated steatohepatitis (MASH). Semaglutide, a glucagon-like peptide (GLP)-1 analogue indicated for management of body weight and type 2 diabetes (T2D), is under investigation in MASH. However, T2D seems to reduce GLP-1 analogue-mediated weight loss in people with overweight/obesity.

Aims & Methods: This study evaluated the impact of T2D and other cardiometabolic parameters on weight loss in randomised controlled trials of subcutaneous semaglutide in MASLD including MASH. Data were taken from adults in NCT03357380 (MASLD; semaglutide 0.4 mg or placebo once daily [OD] for 72 weeks), NCT02970942 (MASH and fibrosis stage [F] 1–3; semaglutide 0.1, 0.2 or 0.4 mg or placebo OD for 72 weeks) and NCT03987451 (MASH, F4 and compensated liver cirrhosis; semaglutide 2.4 mg or placebo once weekly [OW] for 48 weeks). This post-hoc analysis pooled data for semaglutide

(0.4 mg OD and 2.4 mg OW) and placebo, with weight changes grouped by baseline T2D status (previously diagnosed or glycated haemoglobin [HbA1c] $\geq 6.5\%$, pre-T2D [HbA1c $\geq 5.7 - < 6.5\%$] or no T2D [HbA1c $< 5.7\%$]). Mean on-treatment changes from baseline to 1 year were used to derive estimated treatment differences (ETDs) and 95% confidence intervals for semaglutide vs placebo. Impact of cardiometabolic factors including baseline fasting lipids, plasma glucose, diabetes duration and Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) were assessed.

Results: Of the 300 participants included, 209 (70%) had T2D, 51 (17%) pre-T2D and 40 (13%) non-T2D. ETDs ranged from – 9.8 kg in the pre-T2D group to – 11.6 kg in the non-T2D group; there was no significant difference between the non-T2D vs pre-T2D, pre-T2D vs T2D and non-T2D vs T2D groups in terms of weight change (Table). Weight change was not influenced by known diabetes duration, or baseline HOMA-IR or glucose and lipid levels.

Conclusion: Unlike previously reported differences in weight change in people with and without T2D, the presence of T2D did not influence efficacious weight loss with semaglutide in individuals with MASLD including MASH.

Introduction: Currently, there is no approved medication for the treatment of Metabolic Associated Fatty Liver Disease (MASLD). However, numerous clinical trials have examined the effect of antihyperglycemic agents on MASLD in type 2 diabetic (T2D) patients, given the close association between T2D and this hepatopathy, both of which are closely linked to insulin resistance.

Our aim is to evaluate and compare the therapeutic effects of different hypoglycemic agents in patients with MASLD and T2D.

Aims & Methods: This is a prospective cross-sectional study involving 200 T2D patients over a 6-month period. The presence of hepatic steatosis was confirmed by abdominal ultrasound and/or a Fatty Liver Index (FLI) score greater than 60 in 122 patients. Hepatic fibrosis was assessed using FibroScan in all patients with MASLD. Two comparative studies were conducted to identify the therapeutic effects of hypoglycemic medications on hepatic steatosis and significant fibrosis, defined by a LSM value ≥ 8 kPa.

Results: Patients were predominantly female (73.2%) with a median age of 59.76 ± 10 years. The duration of T2D, although longer in cases of steatosis, was not statistically significant. Glycemic control, assessed by fasting blood glucose and HbA1c levels, was less optimal in patients with MASLD, with an average HbA1c level of 8.98%, compared to patients without hepatic steatosis, who had an average HbA1c level of 8.74% ($p=0.002$). A similar trend was observed with fasting blood glucose levels (81.96% vs 73.07%), but it did not reach statistical significance.

Degenerative complications, regardless of their type, were comparable between the two groups.

The prescription of biguanides was associated with a reduced risk of hepatic steatosis ($p=0.05$), while insulin use was frequently observed in patients with steatosis, with a statistically significant correlation for long-acting human insulin and rapid-acting analogs (33.61% vs 19.23% in the absence of steatosis, $p=0.02$) and (4.92% vs 0% in the absence of steatosis, $p=0.05$) respectively. No other therapeutic modality, including different classes of oral antidiabetic agents, was correlated with the risk of steatosis.

The prescription of sulfonylureas and rapid-acting insulin analogs was associated with a higher risk of significant hepatic fibrosis, with p -values of 0.05 and 0.008 respectively. In contrast, the use of long-acting human insulin was less frequent in patients with significant fibrosis, with a statistical correlation of 0.03. No other treatment modality, including various types of oral antidiabetic agents, was associated with the risk of fibrosis.

Conclusion: The use of biguanides appears to reduce the risk of hepatic steatosis, while insulin therapy, particularly rapid-acting analogs, is associated with an increased risk of hepatic steatosis and fibrosis. These observations emphasize the importance of an individualized therapeutic approach to optimize the management of MASLD in type 2 diabetic patients. Further studies are needed to validate these associations

Introduction: MAESTRO-NASH (NCT03900429) is an ongoing 54-month, randomized, double-blind, placebo-controlled Phase 3 trial evaluating the efficacy of resmetirom in patients with biopsy-confirmed nonalcoholic steatohepatitis (NASH) and fibrosis. 966 patients with biopsy confirmed NASH were randomized 1:1:1 to resmetirom 80 mg, resmetirom 100 mg, or placebo administered once daily. Histologic endpoints were assessed after 52 weeks. Dual primary endpoints at Week 52 were achieved with both resmetirom 80 mg and 100 mg: NASH resolution with no worsening of fibrosis (NR) or ≥ 1 -stage reduction in fibrosis with no worsening of NAS (FI). Body weight is the major factor influencing exposure to resmetirom in patients with NASH/MASH.

Aims & Methods: This post-hoc analysis was performed to provide additional evidence of a relationship between resmetirom dose, baseline body weight and body mass index (BMI) and to assess the impact of baseline body weight and BMI on resmetirom response, we

stratified resmetirom efficacy data on the dual endpoints based on baseline patient body weight (≤ 100 and >100 kg) and BMI (≥ 35 and <35 kg/m²).

Results: For patients treated with resmetirom 80 mg who weighed ≤ 100 kg, the 30% PDFF response was 66.9%; and in patients with a Week 52 biopsy, 35.4% showed fibrosis improvement (FI) compared with 32% who showed no worsening of fibrosis (NR). In patients >100 kg, the 30% PDFF response was 56.7%; FI=22.5%; and NR=27%. For patients who received resmetirom 100 mg who were ≤ 100 kg, the 30% PDFF response was 71.7%; FI was 33.6% and NR was 35.8%; for patients >100 kg, PDFF=72.5%; FI=32.5%; NR=35.8%. Increases in FI were noted relative to placebo for patients who received resmetirom 80 mg (mITT population) who had BMI <35 : 13.0% (5.2, 20.8); NR=33.4% (14.2, 30.6); and in patients with BMI ≥ 35 : FI=7.0% (-0.7, 14.7); NR=9.8% (3.1, 16.6). Increases were also noted relative to placebo for patients who received 100 mg of resmetirom (mITT population) who had a BMI <35 : FI=11.8% (4.2, 19.4) NR=21.0% (13.4, 28.7); for patients with BMI ≥ 35 : FI=11.1% (3.4, 18.9); NR=20.0% (12.3, 27.7).

Conclusion: As shown in these stratified data, resmetirom 100 mg was consistently more effective than 80 mg in achievement of the dual primary endpoints in the sample of patients who had higher baseline body weight

and BMI. In patients with a lower BMI, there was no observed difference in efficacy between the 80 and 100 mg resmetirom doses.

Introduction: Cardiovascular (CV) risk is increased in people living with metabolic dysfunction-associated steatohepatitis (MASH). Although liver biopsy remains the gold standard to diagnose MASH, it is not practical to implement on a large scale. However, non-invasive tests, such as the Fibrosis-4 score (FIB-4), are useful for staging patients with fibrotic MASH and predict overall, CV- and liver-related mortality. In the SELECT CV outcome trial, which included patients with a body mass index ≥ 27.0 kg/m² and established CV disease but without diabetes, those treated with the glucagon-like peptide-1 receptor agonist semaglutide had a 20% CV risk reduction compared with those receiving placebo. We examined the CV benefits of semaglutide in a subgroup of participants at high risk of MASH as defined by FIB-4.

Aims & Methods: SELECT was a multicentre, randomised, double-blind, placebo-controlled, event-driven trial that enrolled 17,604 patients aged ≥ 45 years. Patients were randomly assigned in a 1:1 ratio to receive once-weekly subcutaneous semaglutide 2.4 mg or placebo in addition

to standard of care recommendations for CV disease prevention. This subgroup analysis for the primary composite endpoint of 3-point major adverse cardiovascular event (MACE; non-fatal myocardial infarction, non-fatal stroke, CV death) was performed for patients with increased MASH risk as indicated by FIB-4 ≥ 1.3 for patients aged < 65 years and FIB-4 ≥ 2.0 for patients aged ≥ 65 years, and for a second subgroup of patients of any age with FIB-4 > 2.67 , respectively. As identified by review of medical history and co-medication, patients with a cause of liver disease other than MASH were not included in this analysis.

Results: From the SELECT cohort, 3,665 patients (20.8% of all) aged < 65 years with FIB-4 ≥ 1.3 and aged ≥ 65 years with FIB-4 ≥ 2.0 were included in this analysis. The primary CV endpoint occurred in 140 of the 1,834 patients (7.6%) in the semaglutide group and in 176 of the 1,831 patients (9.6%) in the placebo group (hazard ratio [HR] 0.79; 95% confidence interval [CI] 0.63, 0.98; $p < 0.03$). In the subgroup of 475 patients with suspected MASH and advanced fibrosis (FIB-4 > 2.67 irrespective of age), there were 22 CV events in 235 patients treated with semaglutide 2.4 mg compared with 35 events in 240 placebo-treated patients, yielding an HR of 0.64 (95% CI 0.37, 1.08; $p = 0.10$).

Conclusion: In line with the primary analysis of the SELECT trial, use of semaglutide 2.4 mg in a subgroup of patients at high risk of fibrotic MASH as defined by FIB-4 produced a 21% reduction in MACE outcomes.

Introduction: Semaglutide, a glucagon-like peptide-1 receptor analogue approved for treatment of type 2 diabetes (T2D) and overweight or obesity, is being investigated as a potential treatment for patients with metabolic dysfunction-associated steatohepatitis (MASH). Here, we present safety data from two phase 2 trials of subcutaneous semaglutide in patients with MASH with or without compensated cirrhosis.

Aims & Methods: This was a *post-hoc* analysis of two trials: NCT02970942 (320 patients with fibrosis stage F1–3 randomised 3:1 to once-daily semaglutide 0.1, 0.2 or 0.4 mg [n=80, 78 and 82] or placebo [n=80] for 72 weeks) and NCT03987451 (71 patients with compensated cirrhosis randomised 2:1 to once-weekly semaglutide 2.4 mg [n=47] or placebo [n=24] for 48 weeks). Patients received diet/lifestyle advice in both trials. Safety data were analysed descriptively.

Results: In NCT02970942, 18 patients discontinued semaglutide due to adverse events (AEs), with a similar proportion of patients discontinuing in the semaglutide 0.4 mg (5%; 4/82) and placebo arms (5%; 4/80). In NCT03987451, three patients from the semaglutide arm (6.4%) discontin-

ued due to AEs. In both trials, gastrointestinal (GI) disorders were the most common AEs with semaglutide (64–77% vs 33–45% with placebo); most GI AEs with semaglutide were non-serious and mild (55–71%) or moderate (22–36%). The proportion of patients with GI AEs with semaglutide in the MASH trials (63.8–76.9%) was similar to that seen in the weight management program STEP (63.5–82.8%), but higher than in the T2D development program SUSTAIN (34.4–52.0%).

There were no reported cases of acute pancreatitis. Overall, the proportion of patients with hepatic AEs (most frequently reported [in 0–3 patients per arm]: blood bilirubin increased, alanine transaminase increased, hepatic enzyme increased, international normalised ratio increased, transaminases increased, ascites) was 8–11% with semaglutide versus 4–14% with placebo. Few gallbladder-related AEs were reported. Four cholelithiasis events occurred in the semaglutide arms in the two trials; three were serious, of which two led to cholecystitis or cholangitis. All three serious events resolved with cholecystectomy. No cases of drug induced liver injury were reported. Throughout the trials (up to 72 weeks), three patients in the semaglutide group reported malignant neoplasms (breast cancer, endometrial adenocarcinoma and peripheral T-cell lymphoma) vs none with placebo; all events were judged as unlikely to be related to semaglutide.

Conclusion: Data from two phase 2 trials indicate that semaglutide is generally well tolerated in patients with MASH, including those with compensated cirrhosis. No new safety concerns were identified, and the safety profile was similar to that in patients with T2D and overweight/obesity. Data from the ongoing phase 3 trial (NCT04822181) will provide further knowledge about the safety of semaglutide in patients with MASH.

Introduction: Metabolic dysfunction-associated steatotic liver disease (MASLD) presents as a complex multifactorial disease, in which dysregulation of metabolic homeostasis in the liver, as well as in distant organs, plays a substantial role. Recent evidence places skeletal muscle and the muscle-liver axis at the center of the MASLD pathogenic cascade. In fact, low muscle mass and muscle fat infiltration associates with increased risk of advanced MASLD, namely metabolic-associated steatohepatitis (MASH). In parallel, we showed that microRNA-21 (miR-21) is increased in the liver and skeletal muscle of MASH patients, with its abrogation ameliorating disease progression in vivo.

Aims & Methods: Here, we investigated the effects of miR-21 on muscle function in the context of experimental MASLD. *Mir21* whole body knock-out (KO); *Mir21*Alb-Cre KO (hepatocyte-specific KO) and wild-type (WT) mice were fed ad libitum with a high-fat/calorie diet (HFD) with high fructose/glucose corn syrup in drinking water for 20 weeks, or with a standard diet (SD), to recapitulate key, complementary metabolic features of human MASLD. Muscle phenotype and function were evaluated through grip strength and wheel running assays one week before sacrifice. In parallel, glucose tolerance test was also performed. At sacrifice, liver/muscle biopsies and total serum were collected for subsequent analyses.

Results: Both *Mir21*Alb-Cre KO and *Mir21* KO HFD-fed mice displayed significant lower weight increments throughout time, compared to WT HFD-fed mice. Moreover, all HFD-fed mice presented reduced voluntary wheel-running distance, except for *Mir21*KO HFD-fed mice, which showed SD-like wheel-running distance. *Mir21* KO mice also displayed a tendency to have grip strength levels higher than WT mice. Furthermore, both *Mir21*Alb-Cre KO and *Mir21* KO HFD-fed mice had AUC of glucose significantly lower than WT HFD-fed mice, and that was similar to WT SD-fed mice. In agreement, *Mir21* KO HFD-fed mice showed increased mRNA levels of MyoD and Pax7, two transcription factors responsible for the development and regeneration of skeletal muscle through the differentiation of myoblasts into myotubes, thereby counteracting the decrease observed in WT HFD-fed mice. Moreover, both *Mir21*Alb-Cre KO and *Mir21* KO HFD-fed mice had significantly decreased mRNA expression levels of *Mafbx* (atrofina-1), a ubiquitin ligase responsible for marking muscle cell proteins for degradation, when compared with WT mice.

Conclusion: Our results show that *Mir21* KO mice on a high-fat diet exhibit higher skeletal muscle function compared to their WT counterparts, further suggesting that the ablation of miR-21 contributes to muscle regeneration while inhibiting muscle degradation. These findings highlight the relevance of the muscle-liver axis in MASLD pathogenesis and, possibly, therapeutic targeting. (2022.08837.PTDC, FCT).

THE EFFECT OF SGLT2 INHIBITORS ON HEPATIC STEATOSIS DETECTED BY MRI-PDFF IN PATIENTS WITH TYPE 2 DM AND METABOLIC ASSOCIATED STEATOSIS LIVER DISEASE

M.A. Amin¹, N. Adly¹, H. Saad¹, M. Fawzi², H. Abdallah Elsheimy¹
¹Cairo University, Internal Medicine, Giza, Egypt, ²National liver institute, Radiology, Cairo, Egypt

Contact E-Mail Address: monasleman@hotmail.com

Introduction: Metabolic associated steatosis liver disease (MASLD) is the new nomenclature of non-alcoholic fatty liver diseases (NAFLD) which highlights its crucial effect on the cardiometabolic risk factors that lead to the development and progression to liver diseases. Recently SGLT2 inhibitors have been identified to reduce hepatic steatosis in patients with T2DM with MASLD

Aims & Methods: Our aim was to assess the effect of SGLT2 inhibitors on hepatic steatosis in patients with T2DM and MASLD, we enrolled 30 diabetic adults with hepatic steatosis on ultrasound confirmed and quantified by baseline magnetic resonance proton density fat fraction (MRI-PDFF) they started SGLT2 inhibitors added to the standard of care treatment for 6 months and assessment of the percentage change of hepatic steatosis with done by repeat MR-PDFF.

Results: There were statistically significant decreases in the mean body weight and BMI after treatment (86.7Kg, 33.313 Kg/m²) respectively compared to their levels before treatment (90.367kg, 35.144 Kg/m²) respectively, $P < 0.001$. Moreover, the mean serum fasting blood sugar and alanine transaminase decreased significantly after treatment (209.267, 22.633) compared to levels before treatment (220.566, 28.03) ($P = 0.017$, $P = 0.03$) respectively.

Regarding hepatic steatosis there was a statistically significant decrease in the mean MRI-PDFF measurement for hepatic steatosis after treatment (13.297 $\pm$ 7.15) compared to the mean levels before treatment (15.288 $\pm$ 8.72) with a mean difference (-1.9911, $P = 0.006$) of about 13.16% decrease of steatosis

Conclusion: Addition of SGLT2 inhibitors to the standard treatment in type 2 diabetic patients with MASLD could reduce the hepatic steatosis significantly after 6 months of treatment associated with decrease in body weight, BMI, fasting blood sugar. Thus, the therapeutic use of SGLT2 inhibitors is valuable in type 2 diabetic patients associated with MASLD

EFFECT OF SAROGLITAZAR ON METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE RELATED EARLY FIBROSIS AND STEATOSIS- A PROSPECTIVE, SINGLE CENTRE, REAL WORLD STUDY

R. Singh¹, G. Baweja²

¹J P Medical Centre, Gastroenterology, Chandigarh, India,

²J P Medical Centre, Chandigarh, India

Contact E-Mail Address: drrajdeep@gmail.com

Introduction: The new nomenclature of Non alcoholic fatty liver disease (NAFLD) as metabolic dysfunction-associated steatotic liver disease (MASLD), has an excellent concordance and 99% of individuals with NAFLD meet MASLD criteria. MASLD is becoming the most rapidly increasing contributor to the disease burden related to adverse liver outcomes, including cirrhosis, liver failure, and HCC. To curb this rising tide of MASLD (38.2% global prevalence), an early comprehensive and efficient management strategies are very crucial. Saroglitazar, a novel dual PPAR α/γ agonist operates through a multifaceted mechanism of action, targeting

key pathways driving the progression of MASLD, and have shown benefits at different stages of disease ranging from early to advance fibrosis and compensated cirrhosis.

Aims & Methods: We tried to evaluate the effect of Saroglitazar in MASLD associated early fibrosis, in a population where majority did not have diabetes and hypertension at baseline.

A prospective, real world study was conducted at a single centre setting in North India with 67 patients showing ultrasonographic evidence of fatty liver changes and dyslipidemia. Transient elastography was performed to reliably exclude advanced liver disease and treatment progression at 3 and 6 months after Saroglitazar 4 mg OD prescription. The Controlled Attenuation Parameter (CAP) and liver stiffness measurement (LSM) were assessed as primary treatment endpoints along with other markers of liver function and metabolic health as secondary efficacy parameters. Changes were evaluated using paired t-tests, from baseline to the 12 and 24 week mark. This rigorous methodology allowed for a comprehensive assessment of Saroglitazar's impact on both liver health and metabolic parameters.

Results: The 67 patients, who followed the study inclusion criteria and treated with Saroglitazar 4 mg OD, were evaluated on primary and secondary efficacy parameters. They had the mean age 50.34 ± 11.69 and mean body weight 82.1 ± 11.9 . Among them, 61.2% are males, 88.1% non diabetic, 89.6% non hypertensive, and 83.6% are not having any family history of NAFLD. 57.8% of them had F0-F1 fibrosis and 34.4% had F2 fibrosis at baseline. The mean reduction in CAP was 34.7 ($p < 0.001$) and 38.7 dB/m ($p < 0.001$) and mean reduction in LSM was 0.53 ($p = 0.043$) and 1.31 Kpa ($p < 0.001$), respectively at 12 and 24 weeks ($n = 32$). A significant and consistent reduction in AST, ALT, TG, LDL and HbA1c was also seen. No new safety signals were observed.

Parameters	Baseline Median (IQR)	12 Weeks (Mean change)	% Change	p value	24 Weeks (Mean change)	% change	p value
Weight (in Kg) (n=58)	80.5 (14.0)	-4.11	-5.01	0.0524	-5.2 (n=32)	-6.2	0.072
HbA1c (n=62)	6.6 (0.38)	-0.3	-4.54	<0.001	-0.55 (n=27)	-7.96	0.0014
LDL (n=62)	134 (65.0)	-35.37	-24.80	<0.001	-37.9 (n=19)	-24.6	<0.001
TG (n=58)	198.0 (82.0)	-59.91	-27.70	<0.001	----	----	----
SGOT (n=59)	52 (34.5)	-23.51	-38.04	<0.001	-27.7 (n=34)	-40.9	<0.001
SGPT (n=59)	58 (42.0)	-26.05	-39.12	<0.001	-39.5 (n=34)	-46.8	<0.001
CAP (n=64)	296.5 (34.3)	-34.67	-11.79	<0.001	-38.7 (n=32)	-13.2	<0.001
LSM (n=64)	7.4 (1.4)	-0.53	-6.85	0.0430	-1.31 (n=32)	-15.8	<0.001

Table: Absolute and percentage mean changes in Primary and secondary study parameters at 12 and 24 weeks.

Conclusion: Treatment with Saroglitazar 4 mg significantly reduces liver stiffness and steatosis, improves liver enzymes, and other metabolic parameters like serum glucose and lipid profile. It could be a crucial treatment component for an early comprehensive and efficient management of MASLD and helpful in curbing the rising tide of global MASLD burden. Saroglitazar treatment was safe.

DOUBLE GUIDE-WIRE TECHNIQUE VERSUS TRANSPANCREATIC BILIARY SPHINCTEROTOMY FOR DIFFICULT BILIARY CANNULATION: A RANDOMIZED CONTROLLED TRIAL

K. Amalou¹, N. Benboudiaf¹, K. Saidani¹

¹HCA, Gastroenterology, Algiers, Algeria

Contact E-Mail Address: amalou_kh@yahoo.fr

Introduction: During endoscopic retrograde cholangiopancreatography (ERCP) for biliary indication, difficult biliary cannulation with an unintended access to the main pancreatic duct (PD) increases the risk of post-ERCP pancreatitis (PEP). Both double guidewire technique (DGW) and transpancreatic biliary sphincterotomy (TPBS) can be performed.

Aims & Methods: The purpose of this prospective, randomized, controlled trial is to compare the technical success and adverse events (AEs) rate of these techniques.

Method: Patients with native papilla and planned CBD cannulation were recruited from January 2021 and July 2023. An experienced endoscopist attempted CBD cannulation with wire-guided cannulation. If the procedure fulfilled the definition of difficult cannulation and a guidewire entered the pancreatic duct, randomization to either TPBS or to DGW was performed. If the randomized method failed, any method available was performed. The primary end point was the frequency of PEP and the secondary end points included successful cannulation with the randomized method.

Results: Overall, 1082 patients were recruited and 202 patients (56.3% males, mean age 64.2 years) were evaluated (98 DGW, 104 TPBS). Malignant biliary stricture was the most common ERCP indication (58.2%). The rate of success in deep biliary cannulation was significantly higher in the TPBS group (96.1%) compared to DGW(81.2%) at the first attempt ($p = 0.01$). No significant difference in AEs rate, particularly in PEP incidence was found between the two groups. PEP developed in 14/104 patients (13.5 %) in the TPBS group and 16/98patients (16.1 %) in the DGW group ($P = 0.71$). No difference existed in PEP severity between the groups.

Conclusion: In difficult biliary cannulation, TPBS demonstrated a higher success rate and similar safety profile compared with DGW. there was no difference in PEP rate between TPBS and DGW techniques. TPBS is a good alternative in cases of unintended PD cannulation of difficult cannulation.

Disclosure: Nothing to disclose.

Introduction: Previous case reports and studies have shown frailty to be a risk factor for complications and poor outcomes following surgeries and endoscopic procedures. However, limited studies have examined the impact of frailty on endoscopic retrograde cholangiopancreatography (ERCP). Our study aims to compare patients undergoing ERCP with frailty to those without ERCP to understand the impact of frailty on ERCP better.

Aims & Methods: The NIS is a large, publicly available all-payer inpatient care database in the USA and was queried. We retrospectively analyzed the Nationwide Inpatient Sample (NIS) database for 2015-2019. Patients with a principal diagnosis of ERCP with and without frailty were identified using the ICD-10 codes. Multivariate regression analysis was used to calculate the odds ratios of in-hospital mortality, the average length of hospital stay (LOS), and hospital charges (TOTHC) using STATA 17 MP.

Results: Our study identified approximately 1,088,175 patients undergoing ERCP, of which 1,700 were frail.

On multivariate analysis, in patients undergoing ERCP and frailty as a co-morbidity, positive predictors of increased mortality were the following: sepsis (OR: 9.95, $p < 0.0001$, 95% CI: 2.95 - 16.95), acute kidney injury (AKI) (OR 5.63, $p < 0.0001$, CI 4.64 - 6.82), malnutrition (OR 3.28, $p < 0.0001$, CI 2.66 - 4.04), post-procedural bleeding (OR 2.85, $p < 0.0069$, CI 1.95 - 3.70), aspiration (OR 4.94, $p < 0.0001$, CI 2.59 - 6.80), congestive heart failure (CHF) (OR 1.48, $p < 0.001$, CI 1.19 - 1.86).

LOS was increased if patients had any of the following complications: sepsis (+2.86 days, $p < 0.0001$, 95% CI: 2.59 - 3.13), AKI (+3.44 days, $p < 0.0001$, 95% CI: 3.16 - 3.73), malnutrition (+6.44 days, $p < 0.0001$, CI 5.89 - 6.99), post-procedural bleeding (+4.99 days, $p < 0.0001$, CI 3.29 - 6.68), aspiration (+9.87 days, $p < 0.0001$, 95% CI 7.48 - 12.27), or CHF (+1.87 days, $p < 0.0001$, CI 1.53 - 2.22).

TOTHC were increased in patients who had the following complications: sepsis (\$46,978, $p < 0.0001$, CI \$41,364 - \$52,593), AKI (\$53,007, $p < 0.0001$, CI \$44,221 - \$61,793), malnutrition (\$85,454, $p < 0.0001$, \$64,515 - \$106,393), post-procedural bleeding (\$114,168, $p < 0.0001$, \$61,465 - \$166,871), aspiration (\$198,071, $p < 0.0001$, \$113,911 - \$282,230) or CHF (\$20,191, $p < 0.0001$, \$12,983 - \$27,398).

Conclusion: Based on our study results, those with ERCP who had a co-morbidity of frailty had increased mortality, LOS, and TOTHC with the following complications: sepsis, AKI, malnutrition, post-procedural bleeding, aspiration, and CHF. While frailty is not a contraindication to doing an ERCP, our study demonstrates that there must be close monitoring and preparation of these patients before ERCP to avoid complications because many complications significantly increase mortality. This is a high-risk patient population. Randomized trials will be required to further study the impact of frailty on ERCP.

INTEROBSERVER VARIABILITY IN LYMPH NODE EVALUATION WITH ENDOSCOPIC ULTRASONOGRAPHY IN PERIHILAR AND INTRAHEPATIC CHOLANGIOCARCINOMA

D.M. de Jong¹, D. Roosterman¹, M.J. Bruno¹, L.M. van Driel¹, W.J. Lammers¹

¹Erasmus MC University Medical Center, Gastroenterology & Hepatology, Rotterdam, Netherlands

Contact E-Mail Address: d.m.dejong@erasmusmc.nl

Introduction: Surgery is the only curative treatment option for patients with intrahepatic and perihilar cholangiocarcinoma (CCA) without metastatic disease in lymph nodes (LNs) and beyond. Therefore, pre-operative staging is crucial for appropriate treatment decision-making [1]. Endoscopic ultrasound (EUS) is a promising technique to assess LN preoperatively to find proof of metastatic disease in addition to regular scans [2-5]. Although specific LN characteristics have been recognized as important predictive factors for metastatic disease in hepatobiliary disease in general, inter-observer agreement is suggested to be poor. This study aims to assess interobserver agreement among endosonographers evaluating LN characteristics specifically in intrahepatic cholangiocarcinoma (iCCA) and perihilar cholangiocarcinoma (pCCA).

Aims & Methods: A cross-sectional survey study involving 145 endosonographers from the Netherlands as well as the POELH-trial (NCT05678218) was conducted. Participants reviewed 42 randomly selected de-identified EUS images of LNs in a web-based survey. The primary outcome of this study was to assess the interobserver agreement of LN characteristics among endosonographers. In addition, it was evaluated how concordant endosonographers judged LNs to be malignant. Interobserver agreement was evaluated using Light's kappa for the following LN characteristics: demarcation, shape, echogenicity, homogeneity, suspicion of malignancy and retrieving tissue. Subgroup analyses were performed for experts vs. non-experts (>1000 vs. <1000 EUS procedures), and experienced vs. non-experienced (15-30 years vs. 0-15 years). Diagnostic accuracy, sensitivity and specificity were determined based on a 2x2 table where presumed suspicious/not suspicious (based on EUS characteristics) was plotted against definite benign/malignant (EUS-fine needle aspiration/biopsy or surgical specimen pathology).

Results: Twenty-four endosonographers (16.6%) completed the survey. Participants showed fair to moderate agreement on EUS features with Light's kappa values of 0.24 for demarcation, 0.45 for shape, 0.38 for echogenicity, 0.52 for homogeneity, 0.36 for suspiciousness and 0.27 for performing FNA/B. Subgroup analyses suggest that experts and experienced endosonographers showed higher agreement on LN characteristics compared to non-experts and non-experienced endosonographers. The overall visual diagnostic accuracy for suspecting malignancy in LNs was 64%, ranging from 45 to 76%.

Conclusion: This study shows a fair to moderate inter-observer agreement of LN characteristics as well as a moderate rate of correct assessment of malignant LNs. among both expert and non-expert endosonographers. These findings support the justification to biopsy all LNs as carried out in the POELH trial (NCT05678218).

EUS-CHOLEDOCHODUODENOSTOMY VERSUS HEPATICOGASTROSTOMY COMBINED WITH EUS-GASTROENTEROSTOMY IN MALIGNANT DOUBLE OBSTRUCTION (CABRIOLET_PRO): A PROSPECTIVE COMPARATIVE STUDY

G. Vanella^{1,2}, R. Leone^{1,2}, F. Frigo^{1,2}, G. Dell'Anna^{1,2}, M. Reni^{2,3}, L. Aldrighetti^{2,4}, M. Falconi^{2,5}, G. Capurso^{1,2}, P.G. Arcidiacono^{1,2}

Introduction: Combined Biliary (BO) and Gastric Outlet Obstruction (GOO) represent a challenging clinical scenario. Previous retrospective experiences have demonstrated shorter Dysfunction-Free survival (DFS) of EUS-guided Choledochoduodenostomy (EUS-CDS) versus EUS-Hepatogastrostomy (EUS-HGS) in this scenario, but no prospective evidence is available.

Aims & Methods: All consecutive patients treated for double obstruction between 2021-2023 were eligible for inclusion upon receiving EUS-guided Gastroenterostomy (EUS-GE) for GOO and either EUS-CDS or EUS-HGS for BO according to endoscopist preference. DFS prospective surveillance started from the day the 2 procedures coexisted. Efficacy and safety were evaluated, with biliary dysfunctions as primary outcome and DFS using Kaplan-Meier estimates (with log-rank test) as primary measure.

Results: Twenty patients (75% with pancreatic cancer, 50% with metastatic disease) with EUS-GE were included (7 EUS-CDS and 13 EUS-HGS). No significant difference was detected at baseline. Technical success was 100% in both groups. EUS-CDS versus EUS-HGS showed similar clinical success (100% vs. 92.3%, $p=0.5$), a higher rate of post-procedural adverse events (42.9% vs. 7.7%, $p=0.067$, mostly related to severe/fatal cholangitis in the EUS-CDS group) and a higher rate of biliary dysfunctions during follow-up (57.1% vs. 16.7%, $p=0.074$).

DFS was significantly shorter in the EUS-CDS group (39 [12-66] vs. 267 [192-344] days, $p=0.0043$), with a 30-days probability of DFS of 53.6% vs. 100%, $HR=7.4$ [1.1-52.3].

Conclusion: In this prospective comparison of patients with malignant double obstruction undergoing EUS-GE, treating jaundice with EUS-CDS versus EUS-HGS resulted in reduced probability of survival without biliary events, with detection of severe/fatal cholangitis.

Introduction: EUS-guided biliary drainage, including choledoco-duodenostomy (EUS-CD) and transmural gallbladder drainage (EUS-GD), is an emerging alternative to ERCP for the treatment of malignant distal biliary obstruction (MBO).

Aims & Methods: The aim of our study was to compare the efficacy of EUS-CD and EUS-GD in the treatment of MBO. **METHODS:** We identified patients with MBO who underwent either EUS-CD or EUS-GD using a prospective EUS registry. The procedures were performed using Pentax linear echoendoscopes attached to a HITACHI system. Lumen Apposing Metal Stents (LAMS) of 6x8 mm or 8x8 mm were used for EUS-CD and 10x10 mm for EUS-GD. The primary outcome was clinical success, defined as at least a 50% reduction in serum bilirubin levels at 2 weeks. Secondary outcomes included adverse events (AE) and stent occlusion (SO) rates. Data are presented as median (range), frequencies and percentages. Statistical analysis was performed using chi-squared or Fisher's test and Student t test or U-Mann-Whitney test as appropriate.

Results: A total of 42 patients were included in the study (mean age 73.5 years [range 50-90 years], 24 males). Pancreatic adenocarcinoma was diagnosed in 81% of patients, of which 78.6% were unresectable. The clinical characteristics of the patients were similar between the two groups. The common bile duct (CBD) size was 16.7 mm (11.5-25 mm) in the EUS-CD group and 10.3 mm (6-13 mm) in the EUS-GD group. The clinical success rate was 92.6% for EUS-CD and 86.7% for EUS-GD ($p=0.06$). In five cases (four EUS-CD and one EUS-GD) a plastic pigtail stent (PPS) was initially placed through the LAMS. There were 6 AEs in the EUS-CD group (21.8%) (2 bleeding, 2 infections) and 5 in the EUS-GD group (33.4%) (1 perforation, 4 infections) ($p=0.45$). Two of the AEs resulted in death. The percentage of SO was 11.1% vs. 40% for EUS-CD and EUS-GD ($p=0.04$).

Conclusion: EUS-CD and EUS-GD are effective techniques for the treatment of MBO. Clinical success and SO rate tend to support EUS-CD over EUS-GD. However, it is important to note that the rate of severe AEs is not negligible. Prospective, comparative, randomised studies comparing these two techniques are needed.

Introduction: Intraductal radiofrequency ablation (RFA) has been proposed as an adjunctive therapeutic method for patients with inoperable perihilar cholangiocarcinoma (pCCA). Because there is limited data regarding the benefits of RFA, we aimed to evaluate the feasibility, efficacy and safety of a RFA based endoscopic palliation protocol.

Aims & Methods: Consecutive inoperable patients presenting biliary obstruction secondary to pCCA were evaluated according to the ongoing, single center, randomized clinical trial (NCT05563870). Native-papilla patients were randomized 1:1 to biliary drainage of the viable liver territories with plastic stents (control) or drainage plus RFA of the entire length of the tumor (active arm). Following index procedure, patients were scheduled for stent exchange and additional RFA treatment (active arm only) at 8-10 weeks intervals. Primary outcome was clinical efficacy defined as bilirubin levels < 3mg/dL at 4 weeks after index ERCP; secondary outcomes included overall survival and safety outcomes.

Results: Heretofore we included 25 patients (13 active arm) undergoing 72 procedures (37 with RFA) for a median follow-up of 3 months (range 2-15). Most patients received either 2 (10/25) or 3 (3/25) plastic stents at index ERCP and 23/25 of the patients reached effective drainage at 4 weeks, only 7 patients receiving undelayed oncologic treatment. There were 11 deaths during follow-up - 6 unrelated to the cholangiocarcinoma, 3 from therapy-related complications and 2 from cancer progression. 20/25 patients experienced at least 1 adverse event - including 15 severe biliary events with no significant differences between the study groups.

Conclusion: Extensive liver drainage followed by iterative stent exchange with intraductal RFA applications seems feasible and effective in the palliation of biliary obstruction in pCCA patients, with no additional risk related to RFA applications. However, adverse events related to biliary infection remain a frequent and life-threatening occurrence during follow-up in this patient population. Further data on the optimal timing and RFA application protocol is required.

Disclosure: No conflict of interest.

Introduction: Biliary adverse events manifest in approximately 25% of liver transplant recipients. Among these, anastomotic biliary strictures (ABS) are the most prevalent, occurring in approximately 6%-12% of cases and can be successfully managed endoscopically.

Aims & Methods: Our study aims to present the evolution of method and long-term results of placing multiple plastic stents to treat ABS after orthotopic liver transplantation (OLT). All consecutive patients who underwent endoscopic retrograde cholangiopancreatography (ERCP) for liver transplantation-related biliary complications at our Endoscopy Unit between July 1994 and September 2022 were retrospectively identified. The analysis focused only on the patients diagnosed with ABS undergoing dilatation by a progressively increasing number of plastic stents. Follow-up after stent removal was obtained by office visit, telephone contact with the patient or referring physician and extended to this year or until patient succumbed.

Results: Two hundred and ninety-five patients referred by 4 Liver Transplant Units underwent ERCP in need of endoscopic treatment for biliary complications after liver transplantation. However only 151 represented our intention-to-treat group with ABS. Out of these, 21 patients were excluded because of split liver transplantation, the use of metallic stents or incomplete endoscopic treatment. The mean age of the remaining 130 patients was 56 ± 9 years old and included 107 males and 23 females. We divided these patients in 2 groups according to similar timeframes, 28 ABS patients being treated before 2008 and 102 patients after 2008. In the first group the median number of stents was 4 (range 2-7), with a median of 3 ERCPs (range 2-5) per patient. Patients treated after 2008 received a median number of 6 stents (range 3-9) (p = .000, Mann-Whitney U), with a median of 4 ERCPs (range 3-7) (p = .002, Mann-Whitney U). The mean treatment duration was 15.3 ± 16.7 months in the first group and 14 ± 10 months in the second. Stricture recurrence was noted in 14.2% of patients treated before 2008 versus 4.9% after 2008. Nevertheless, the follow-up period was 10.6 ± 7.5 years for the first group and 4.7 ± 4 years in the second group.

Conclusion: The endoscopic treatment with multiple plastic stents proved to be effective for the majority of patients with ABS after OLT. In the last decade, the endoscopists shifted towards a more aggressive treatment strategy, with an increased number of stents and a reduced period between stent replacement procedures. This intensive approach seems also to underline a lower stricture recurrence rate however a longer follow-up period needs to be considered for the patients treated after 2008.

Introduction: Endoscopic biliary drainage (BD) in patients with altered anatomy is a challenging scenario reducing the chance of clinical success compared to standard anatomy. The choice between different BD approaches is still not standardized and relies on local availability and expertise.

Aims & Methods: Aim of this study was to explore the type and the number of endoscopic BD approach in patients with altered anatomy in different Italian centers. This was a retrospective multicenter cohort study

within the i-EUS network of biliopancreatic endoscopy. All adult patients with upper GI surgical altered anatomy who underwent endoscopic BD for any indication in the last 5 years were enrolled. Patients with Billroth-I or sleeve gastrectomy were excluded. Patients with duodenopancreasectomy were grouped with patients with BillrothII reconstruction for the statistical analysis. Fisher's exact test and Mann-Whitney test were used when appropriate.

Results:

		Billroth II (263)	Roux-en-Y (165)	p value
Age, years old		81 (72-87)	72 (57-78)	<0.001
Sex	Male	68.2%	57.9%	0.035
	Female	31.8%	42.1%	
Comorbidities	ASA I	4.8%	3.7%	ns
	ASA II	43.2%	43.5%	
	ASA III	46%	47.2%	
	ASA IV	6%	5.6%	
Surgery Indication	Gastric cancer	14.8%	39.6%	0.001
	Pancreatic cancer	14.8%	6.3%	
	Bariatric surgery	0.4%	9.4%	
	Peptic or other benign diseases	60.2%	15.7%	
	OLTx	0%	8.8%	
	Others	9.8%	20.1%	
BD Indication	Benign	75.2%	73.3%	ns
	Malignant	24.8%	26.7%	
Any previous attempt	No	83.1%	82%	ns
	Yes	16.9%	18%	
Endoscopic technique	Device-assisted enteroscopy ERCP	6%	38.8%	<0.001
	Duodenoscope or colonoscope/gastroscope	84.9%	28.7%	
	EUS-BD	7.5%	30.6%	
	Laparoscopic-assisted ERCP	1.6%	1.9%	
Clinical success	No	16.1%	21.1%	ns
	Yes	83.9%	78.9%	
Technical success	No	15.2%	20.5%	ns
	Yes	84.8%	79.5%	

21 centers participated in the study. All centers were equipped for interventional endoscopic ultrasound (EUS) whereas only 7 centers had also the availability of device-assisted enteroscopy (DAE). 428 patients were enrolled. Clinical and BD techniques characteristics of patients are described in table 1. Indication to BD was not different between patients with Billroth-II (B-II, N=263) or Roux-en-Y (RY, N=165) reconstructions. 16% of patients had at least one previous failed BD attempt. B-II anatomies were more frequently managed transpapillary with a duodenoscope or a forward viewing scope (85%), whereas in case of RY reconstruction BD approach was more heterogeneous. In 68% of RY cases endoscopic BD was performed with a luminal approach (in 43% of cases with standard scopes). In patients who underwent to EUS-BD, hepaticogastrostomy or antegrade stenting were performed in 74% of cases mostly for malignant indications (90%). Type of surgical reconstruction did not affect the clinical success (84% in BII and 79% in RY, p=ns). Interventional EUS demonstrated a higher clinical success compared to DAE (94% vs 73%, p=0.004). The total number of procedures to achieve clinical success was similar between B-II and RY patients. Patients who failed endoscopic BD for whom follow-up was available were managed by PTBD or surgery in 71% and 15% of cases respectively.

Conclusion: Endoscopic BD in altered anatomy has a sub-optimal clinical success compared to standard anatomy. A relevant proportion of patients requires more than one endoscopic attempt to achieve the clinical success. Despite the recent advent, interventional EUS is optioned in a significant proportion of patients and demonstrated a high efficacy in patients with surgically altered anatomy.

Disclosure: Nothing to disclose.

Introduction: Endoscopic ultrasound (EUS)-guided choledochoduodenostomy (CDS) is primarily used for biliary drainage in patients with malignant distal biliary obstruction. A recent meta-analysis reported a reintervention rate of 15.8% with EUS-CDS. However, studies analyzing the factors associated with reintervention on follow-up after EUS-CDS are limited.

Aims & Methods: The study aimed to analyze the incidence and predictors of reintervention in patients with malignant biliary obstruction undergoing EUS-CDS. The present study is a retrospective analysis of data from eight tertiary care centers in India from January 2022 to January 2024. Patients aged 18-70 years with malignant distal biliary obstruction undergoing EUS-CDS, with a follow-up duration of more than eight weeks, were included. The study's primary outcome was reintervention, which was required in patients with failure of jaundice to improve due to stent migration or stent blockage during the follow-up, presenting as the worsening of jaundice, with or without cholangitis. The secondary outcomes included clinical success and adverse events. Multivariate analysis using the logistic regression model was used to identify the independent predictors of reintervention.

Results: A total of 140 patients underwent EUS-CDS, out of which 134 patients completed the 8-week follow-up. The median age of the patients was 54.5 (range: 22-90) years, with 53% (71/134) being male. The most common indication for EUS-CDS was inaccessible papilla (59/134, 44.0%), followed by failed cannulation (57/134, 42.5%). The technical success rate was 97.8% (131/134), with placement of self-expanding metal stent (SEMS) in 86.6% (116/134) and lumen-apposing metal stent in 11.2% (15/134). Coaxial double pigtail plastic stent was placed in 19.4% (26/134) cases. Periprocedural adverse events (AE) were seen in 6% (8/134) cases, with severe AE in 0.7% (1/134) cases. Clinical success was achieved in 93.9% (123/131) of the cases with successful stent placement. Over a median follow-up of 20 weeks, reintervention was required in 8.4% of the cases after a median interval of 11 weeks. All patients requiring reintervention could be managed successfully with endoscopic or percutaneous techniques. On multivariate analysis (Table 1), cholangitis at presentation [Odd ratio (OR) 6.26, 95% confidence interval (CI) 1.03-38.09; p =.046] and the absence of coaxial stent with concomitant duodenal stent (OR 7.41, 95% CI: 1.44-38.05; p=.016) were independent predictors of reintervention in the overall cohort. On subgroup analysis of patients undergoing EUS-CDS with SEMS, the absence of coaxial stent with concomitant duodenal stent (OR 10.15, 95% CI: 1.80-57.29; p=.009) was an independent predictor of reintervention.

Parameters	All patients (N = 131)		Only SEMS (N = 116)	
	Odds ratio (95% CI)	p-value	Odds ratio (95% CI)	p-value
Inaccessible papilla	0.85 (0.21 – 3.50)	0.817	0.818 (0.19 – 3.41)	0.782
Cholangitis at presentation	6.26 (1.03 – 38.09)	0.046	5.71 (0.88 – 37.19)	0.068
Baseline bilirubin	1.05 (0.94 – 1.17)	0.386	1.07 (0.94 – 1.21)	0.287
CBD size > 15 mm	3.63 (0.36 – 36.26)	0.273	4.31 (0.37 – 49.82)	0.243
Absence of coaxial stent with concomitant duodenal stent	7.41 (1.44 – 38.05)	0.016	10.15 (1.80 – 57.29)	0.009

Conclusion: Reintervention on follow-up after EUS-CDS is required in around 8.4% of cases, with all cases being managed successfully. The absence of coaxial stent with concomitant duodenal stent was an independent predictor of reintervention in the overall cohort as well as in those undergoing EUS-CDS with SEMS.

Disclosure: Nothing to disclose.

Contact E-Mail Address: gaetanolauri.94@gmail.com

Introduction: Distal malignant biliary obstruction (dMBO) presents a significant clinical challenge, necessitating effective drainage strategies to improve patient outcomes. Various drainage procedures have been utilized, encompassing percutaneous transhepatic biliary drainage (PTBD), endoscopic retrograde cholangiopancreatography (ERCP), or Endoscopic ultrasound-guided biliary drainage (EUS-BD) including EUS choledochoduodenostomy (EUS-CDS). However, the first-line optimal drainage approach remains debated. This network meta-analysis aims to compare the efficacy and safety of different drainage techniques for distal malignant biliary obstruction.

Aims & Methods: We conducted a systematic literature search of randomized control trials (RCTs) comparing different drainage methods as first-line treatment for distal malignant biliary obstruction. MEDLINE database was searched for relevant studies. Studies reporting outcomes such as technical success, clinical success, adverse events, and stent patency were included. Data were extracted, and a network meta-analysis was performed to compare the efficacy and safety of PTBD, ERCP and EUS-BD.

Results: Review of 649 studies yielded 7 RCTs meeting inclusion criteria for quantitative synthesis. These studies were published between 1987 and 2023, with 3 conducted in single centers and 4 at multiple centers, spanning all continents worldwide. They collectively involved 653 patients with distal malignant biliary obstruction. In terms of technical success, EUS-CDS demonstrates a significant superiority over ERCP (risk ratio [RR] 1.17, 95% CI 1.01–1.35), while no significant differences were observed in other comparisons. Furthermore, for clinical success, EUS-CDS outperforms alternative interventions (RR 1.12, 95% 1.02-1.24). Both in terms of technical and clinical success, EUS-CDS ranked the highest (surface under the cumulative ranking [SUCRA] score, respectively 0.90 and 0.86). Conse-

quently, EUS-CDS emerges as the premier treatment modality. Regarding adverse events, PTBD exhibits a pronounced inferiority compared to all other interventions (RR 2.74, 95% CI 1.25–6.02), whereas no statistically significant distinctions were noted among the remaining treatments.

Conclusion: In conclusion, our network meta-analysis suggests that EUS-CDS emerges as the most effective first-line intervention for distal malignant biliary obstruction, demonstrating superior technical and clinical success rates compared to ERCP. Furthermore, PTBD appears to carry a higher risk of adverse events compared to alternative treatments. These results underscore the importance of considering EUS-CDS as the preferred initial drainage approach in clinical practice, with potential implications for improving patient outcomes in this challenging condition.

Introduction: Infections due to Gram-negative bacteria *Helicobacter pylori* (Hp) may result in humans in the development of-gastritis, gastric or duodenal ulcer, and even gastric cancer. Investigation of soluble biomarkers, correlating with Hp infection quantitatively is a promising tool for monitoring the course of infection and related inflammatory response.

Aims & Methods: Aim: The aim of this study was to determine, using an experimental model of Hp infection in guinea pigs, the specific characteristics of infrared spectra (IR) of sera from Hp infected (40) vs. uninfected (20) animals

Material and methods: We employed an *in vivo* guinea pig model after 28 days from inoculation with Hp, corresponding with chronic stage of infection. All animal experiments were carried out according to the agreement with the Local Ethics Committee for Anima Experiments, Medical University of Lodz Poland (Decision 58/ŁB45/2016).

Results: The Hp status in animals was confirmed by histological (the presence of Helicobacter-like organisms, inflammatory response) and molecular (detection of *ureC* and *cagA* sequences by polymerase chain reaction – PCR) examination of gastric tissue and by serological testing of Hp stool antigens and anti-Hp serum antibodies. The IR spectra were measured using a Fourier-transform (FT)-IR spectrometer Spectrum 400 (PerkinElmer) within the range of wavenumbers 3000–750 cm⁻¹ and converted to first derivative spectra. Ten wavenumbers correlated with Hp infection, based on the chi-square test, which were selected for a K-nearest neighbors (k-NN) algorithm. The wavenumbers correlating with infection were identified in the W2 and W3 windows associated mainly with proteins and in the W4 window related to nucleic acids and hydrocarbons. The k-NN for detection of Hp infection has been developed based on chemometric data. Using this model, animals were classified as infected with Hp with 100% specificity and 97% sensitivity.

Conclusion: To summarize, the IR spectroscopy and k-NN algorithm are useful for monitoring experimental Hp infection and related inflammatory response in guinea pig model and may be considered for application in humans.

Financing: The research was financially supported the National Science Center by the grant SONATA 18 “Assessment of the ability of *Mycobacterium bovis* BCG-onco bacilli to control the development of *Helicobacter pylori* infection”, UMO-2022/47/D/NZ7/01097.

THE ROLE OF *HELICOBACTER PYLORI* IN GASTRIC PATHOGENESIS IN COLOMBIA

K. Guzman¹, V. Pabon², A. Hidalgo^{3,4}, A. Pazos^{5,4}

¹Kevin Guzman, Centro de Estudios en Salud Universidad de Nariño (CESUN), San Juan de Pasto, Colombia, ²SENA, Regional Nariño, Semillero de investigación Ciencia para la Vida de Tecnoacademia Túquerres, Túquerres, Colombia, ³Universidad de Nariño, Departamento de Matemáticas, San Juan de Pasto, Colombia, ⁴Universidad de Nariño, Centro de Estudios en Salud Universidad de Nariño (CESUN), San Juan de Pasto, Colombia, ⁵Universidad de Nariño, Departamento de Biología, San Juan de Pasto, Colombia

Contact E-Mail Address: keving346@gmail.com

Introduction: In Colombia, the severity of lesions in gastric cancer pathogenesis varies depending on geographical location (Pacific coast: Low risk; Andean region: High risk), human ancestry, and *Helicobacter pylori* strain. *Helicobacter pylori*, the main causative agent of gastric adenocarcinoma, triggers a proinflammatory Th1 immune response and dysbiosis of the gastric microbiota upon infection by this microorganism.

Aims & Methods: Our research focuses on understanding how the ancestral origins of both *Helicobacter pylori* and humans in Colombia influence the composition and behavior of the gastric microbiota, particularly in relation to the immune response and genetic polymorphisms associated with gastric cancer pathogenesis. Through comprehensive genomic, microbiome, and immunological analyses in individuals with high and low risk of gastric cancer in Colombia.

Results: It was observed that in Colombian Pacific coast reveal a predominant presence of *Helicobacter pylori* strains hspWAfrica and hpAfrica1, aligning closely with the African ancestry of the human population. However, a new strain, hspColombia, is notably present among human individuals of European and Native American descent in the Andean region. Immune responses differ between these regions, with an anti-inflammatory Th2 response prevalent on the Pacific coast, contrasting with a Th1 response observed in the Andean region, linked to specific human polymorphisms such as Mutations *IL-1B-511TT* (72%) and *IL-10-1082AG* (79%). These mutations elevate the risk of developing precursor lesions of gastric cancer by 5.45 times (OR: 5.45; CI: 95%). Comparative analysis of the microbiota indicates a decline in species diversity with increasing severity of gastric lesions due to *Helicobacter pylori* infection. Among the most representative genera of the gastric microbiota were *Helicobacter*, *Pseudomonas*, *Methylobacterium*, *Streptococcus*, *Corynebacterium*, and *Staphylococcus*, as determined by U test (p < 0.001).

Conclusion: The interplay between geographical and genomic variations of *Helicobacter pylori* and humans in Colombia is pivotal in driving the progression of lesions in gastric pathogenesis. The immune response, marked by Th1 and Th2 profiles, exhibits regional disparities and is closely tied to human polymorphisms, notably mutations in the *IL-1B-511TT* and *IL-10-1082AG* genes, which heighten the risk of gastric cancer. *Helico-*

bacter pylori infection modulates the diversity of the gastric microbiota, culminating in a reduction in species diversity as gastric lesion severity escalates. This underscores the significance of maintaining the coevolutionary equilibrium between *Helicobacter pylori* and humans, as its disruption critically impacts dysbiosis in the gastric microbiota, exacerbates proinflammatory immune responses, and contributes to the progression of lesions in the pathogenesis of gastric cancer in Colombia.

Contact E-Mail Address: l.kupcinskas@gmail.com

Introduction: *Helicobacter pylori* (*H. pylori*) infection is the most prevalent type of bacterial infection in the world. Despite significant reduction of prevalence of infection globally, *H. pylori* remains the main cause of chronic gastritis and gastric cancer. Previous studies on *H. pylori* prevalence in Lithuania was performed on small size selective population groups.

Aims & Methods: The aim of the current study was to investigate *H. pylori* seroprevalence in general adult population. The study “Chronic Diseases and their Risk Factors in the Adult Population” involved Kaunas city residents aged 25-64 years, who were randomly selected from the Lithuanian population register lists. The study started in 2020, but was terminated after a quarantine due to COVID-19 infection. It was resumed in 2023. Invitations were sent by post to the selected population to come for a health check-up at Kaunas Clinics, Lithuanian University of Health Sciences Hospital. By 23 June 2023, 1074 people had taken part in the study. An ELISA (SERION ELISA® Classic *H. pylori* IgG, Serion, Germany) was used for the detection of human IgG antibodies to *H. pylori* in blood serum. All subjects were administered a questionnaire that included questions about factors possibly associated with the prevalence of *H. pylori* infection.

Results: *H. pylori* antibodies were tested in the blood serum of 1046 participants, representing 97.4% of the total population. The mean age was 47.2 ± 11.5 years. Standardization of the prevalence of *H. pylori* antibodies according to the age structure of the population of Kaunas city showed that the seroprevalence of *H. pylori* antibodies in males was 66.0%, in females - 59.3%, and in all the subjects - 61.8%. Seroprevalence increased with age in groups of 25-34, 35-44, 45-54, 55-64 yrs and was 49.2%, 62.5%, 71.1%; 67.5%, and 64%, respectively. *H. pylori* antibodies were significantly ($p < 0.05$) more common in subjects with secondary and lower education compared to those with higher and university education. Place of residence during childhood did not influence the prevalence of *H. pylori* infection. Subjects who consumed drinking tap water during childhood were less likely to be infected with *H. pylori*. The prevalence of *H. pylori* antibodies was found to be higher in homes without hot water when growing up. A survey of the participants revealed that previously 17.6 % of them were tested for *H. pylori*, infection was detected in 56.5 %. Medication to eradicate *H. pylori* was used by 132 (84.6%) subjects with a history of infection. In the current study, *H. pylori* antibodies were found in 58.3% of subjects

who had previously taken medication to eradicate the infection, but seroprevalence significantly ($p < 0.05$) decreased with increasing the time since eradication, especially in women.

Conclusion: *H. pylori* IgG antibodies have been detected in a large proportion of adult Kaunas residents aged 25-64 years. High seroprevalence of *H. pylori* in Lithuania (a country with moderate incidence of gastric cancer) raise a question on possible introducing of screen-and-test strategies for *H. pylori* to diminish gastric cancer incidence and mortality.

IMMUNOHISTOLOGICAL ALTERATIONS POST *HELICOBACTER PYLORI* ERADICATION AND THEIR CONNECTION TO METACHRONOUS RECURRENCE IN GASTRIC CANCER

M.-J. Kim¹, J. Chun¹, Y.H. Youn¹, H. Park¹, J.H. Nahm², J.-H. Kim¹

Introduction: *Helicobacter pylori* (*H. pylori*) infection is a significant contributing factor of gastric cancer. Despite advances in early detection and endoscopic resection, metachronous neoplasms still pose a risk. The impact of *H. pylori* eradication on preventing metachronous gastric cancer remains debated, with its underlying mechanisms unclear. This study aimed to investigate immunohistological changes in gastric mucosa after *H. pylori* eradication and identify mechanisms preventing metachronous recurrence.

Aims & Methods: Patients diagnosed with early gastric cancer and *H. pylori* infection, who underwent endoscopic resection, were included. 36 cases of metachronous neoplasms occurring after eradication (metachronous group) were compared to an equal number of controls matched for age, sex, atrophy, and metaplasia (control group). Histological features and immunohistochemical staining for T cell markers (CD3, CD4, CD8), and immune exhaustion markers (Foxp3, PD-L1) were evaluated.

Results: In the control group, chronic inflammation, neutrophil infiltration, glandular atrophy, and intestinal metaplasia in the gastric mucosa significantly improved following *H. pylori* eradication. However, in the metachronous recurrence group, improvement was observed only in chronic inflammation and neutrophil infiltration. CD3 cell counts increased in both groups after eradication, but CD8 and CD8/CD3 ratios saw an increase only in the control group. Additionally, the CD4/CD3 ratio and PD-L1/CD4 expression significantly decreased after *H. pylori* eradication in the control group but not in the metachronous group.

In the subgroup analysis of the metachronous cancer group, which consists of cases with recurrent lesion cancer, CD8, PD-L1, and PD-L1/CD4 ratios showed significant differences when compared to the control group.

Conclusion: *H. pylori* eradication may prevent metachronous recurrence in early gastric cancer by improving histologic inflammation and recovering immune system.

Disclosure: Nothing to disclose.

TRENDS IN THE PRESCRIPTION OF ERADICATION TREATMENTS AND THEIR EFFECTIVENESS IN NAÏVE PATIENTS OVER 11 YEARS (2013-2023) IN EUROPE: DATA FROM THE EUROPEAN REGISTRY ON *HELICOBACTER PYLORI* MANAGEMENT (HP-EUREG)

Introduction: The infection by *H. pylori* can be successfully treated and eradicated if the recommendations from consensus documents are followed correctly. It is essential to continuously assess the applicability of these recommendations to confirm what happens in clinical practice.

Aims & Methods: Multicentre, prospective registry evaluating the decisions and outcomes of *Helicobacter pylori* management by European gastroenterologists. Data were registered at AEG-REDCap e-CRF until December 2023. Modified intention-to-treat (mITT), and time trend analyses were performed.

Results: Overall, 58,334 (82%) were first-line empirical prescriptions. The total number of different therapeutic regimens prescribed exceeded 100. Triple therapy prescriptions decreased from approximately 60% during 2013/15 to 30% in 2023; likewise, non-bismuth concomitant therapy use decreased from 21% in 2013/15 to 15% in 2021/23, while three-in-one single-capsule increased from 0.3% in 2013/2015 to 20% in 2021/23. An increase in the average duration of treatments (from 9.8 days to 12.4 days) in 2013-2023 was identified, as well as in the use of standard/high-dose of PPIs (increasing from 36% to 60%) in 2013-2023. There was a ~10% overall improvement in first-line mITT overall effectiveness from 86% to 94% in 11 years of evolution, both globally and in each geographic region (Table).

Year	2013	2014	2015	2016	2017	2018	2019	2020	2021	2022	2023

Introduction: Eradication treatment containing potassium-competitive acid blocker has shown acceptable eradication efficacy. In regions such as Korea, where the prevalence of antimicrobial resistance is high, alternative combinations of antibiotics such as sequential or concomitant therapy are needed.

Aims & Methods: This study compared the outcome of sequential therapy containing tegoprazan, a new potassium-competitive acid blocker, with the conventional esomeprazole-containing sequential therapy. Patients with *H. pylori* infection were consecutively recruited. Patients were allocated to esomeprazole-containing sequential therapy group, as conventional proton pump inhibitor, or tegoprazan-containing sequential therapy. Sequential therapy consisted of esomeprazole (40 mg) or tegoprazan

(50 mg) plus amoxicillin (1000 mg) twice a day for initial 5 days, and then esomeprazole (40 mg) or tegoprazan (50 mg) with clarithromycin (500 mg) and metronidazole (500 mg) twice a day for the remaining 5 days. Eradication rate, medication compliance, and adverse events were gathered.

Results: A total of 406 patients with *H. pylori* were receive treatment and 406 patients analyzed by per-protocol (Table). The eradication rate by intention-to-treat and per-protocol was 83.8% (95% CI 78.7 – 88.9) for esomeprazole-containing sequential, and 87.1% (95% CI 82.5 – 91.8) for tegoprazan-containing sequential, with no statistical significance ($p = 0.399$). There was also no statistical difference in treatment compliance between the two groups. In tegoprazan-containing sequential, nausea was more prevalent (23.3%, 27/202), which was statistically higher than esomeprazole-containing sequential (14.2%, 29/204) ($p = 0.022$).

	Esomeprazole-containing sequential (n=204) (%)	Tegoprazan-containing sequential (n=202) (%)	p
Age (mean±SD)	61.7±11.6	61.3±11.6	0.731

Introduction: The effectiveness of *H. pylori* treatment decreases as eradication failures accumulate; however, bismuth quadruple therapy with the single-capsule has shown optimal results not only in first but also in second and subsequent lines of treatment, even in patients with dual clarithromycin and metronidazole resistant strains.

Aims & Methods: To evaluate the use and effectiveness of the single-capsule bismuth quadruple therapy when empirically prescribed as retreatment, despite one or multiple previous eradication failures with the same treatment.

All patients registered at e-CRF AEG-REDCap as part of the European Registry on *H. pylori* management (Hp-EuReg) from 2013 to 2023, who had received single-capsule therapy in at least 2 different treatment lines (not necessarily consecutive), were analyzed.

Results: Out of 2,579 patients treated with the single-capsule from 2nd to 6th rescue treatment line, 101 cases received again the same single-capsule therapy at least in 2 different treatment lines: 67 re-treatments in 2nd line having previously failed in 1st line with the single-capsule; 16 re-treatments in 3rd line (of which 12 had previously received this same therapy in 2nd line); 11 in 4th line (previously having failed the same therapy in either 1st, 2nd or 3rd line); 4 in 5th line; and further 3 in 6th line (Table). The effectiveness of bismuth quadruple therapy as single-capsule when empirically prescribed repeatedly in 2nd line was over 90%, and achieved almost 80% in all cases retreated in 3rd line.

Previous failed line, N	2 nd line	3 rd line	4 th line	5 th line	6 th line
1 st line	67	4	3	0	0
2 nd line	0	12	5	1	1
3 rd line	0	0	3	1	0
4 th line	0	0	0	2	2
Total number of cases re-treated	67	16	11	4	3

Effectiveness by modified intention-to-treat of bismuth quadruple rescue therapy as single-capsule when prescribed empirically after previous failure(s) with the same therapy.

Previous failed line, %, (n/N)	2 nd line	3 rd line	4 th line	5 th line	6 th line
1 st line	94%	75% (3/4)	100% (2/2)		
2 nd line	(62/66)	80% (8/10)	75% (3/4)	100% (1/1)	
3 rd line			67% (2/3)	100% (1/1)	
4 th line	94%	79%		50% (1/2)	100% (2/2)
Overall	(62/66)	(11/14)	78% (7/9)	75% (3/4)	100% (2/2)

N: total number of patients analysed; n/N: patients with a successful eradication/total number of patients analysed.

Table. Use of bismuth quadruple rescue therapy as single-capsule when prescribed empirically after previous failure(s) with the same therapy.

Conclusion: The empirical administration of bismuth quadruple therapy as single-capsule when prescribed as re-treatment in 2nd line after previous failure with the same therapy achieves optimal effectiveness (>90%).

Introduction: It is still controversial whether the supplementation of *Saccharomyces boulardii* to bismuth quadruple therapy is beneficial for *Helicobacter pylori* eradication. The aim of the study was to determine the effects of *S. boulardii* supplementation on *H. pylori* eradication.

Aims & Methods: We performed a systematic literature search across PubMed, Embase, Web of Science, and China National Knowledge Infrastructure for articles published up to October 2023. We calculated the pooled relative risk (RR) with the 95% confidence interval (CI). Subgroup analyses were also performed. Statistical analyses were conducted using Stata/SE 15.1 software.

Results: Ten randomized controlled trials were included. Notably, *S. boulardii* supplementation to bismuth quadruple therapy significantly improved *H. pylori* eradication rates (RR = 1.08, 95% CI: 1.04–1.12, $P < 0.0001$) and reduced the incidence of total adverse effects (RR = 0.53, 95% CI: 0.45–0.62, $P < 0.0001$).

Furthermore, it reduced the incidence of some gastrointestinal adverse effects and nonspecific adverse effects, including diarrhea (RR = 0.28, 95% CI: 0.22–0.36, $P < 0.0001$), constipation (RR = 0.32, 95% CI: 0.18–0.55, $P < 0.0001$), abdominal distention (RR = 0.39, 95% CI: 0.26–0.59, $P < 0.0001$), nausea (RR = 0.59, 95% CI: 0.36–0.97, $P = 0.039$), and rash (RR = 0.49, 95% CI: 0.28–0.86, $P = 0.013$). In the subgroup analysis, long-term eradication duration (>10 days; RR = 1.08, 95% CI: 1.04–1.13, $P < 0.0001$) and *S. boulardii* supplementation to be started and stopped at the same time

as bismuth quadruple therapy (RR = 1.09, 95% CI: 1.04–1.14, $P < 0.0001$) were found to significantly improve the eradication rate regardless of the *S. boulardii* dose (500 mg/day, RR = 1.10, 95% CI: 1.03–1.17, $P = 0.003$; 1000 mg/day, RR = 1.08, 95% CI: 1.03–1.12, $P < 0.0001$).

Conclusion: The addition of *S. boulardii* to bismuth quadruple therapy significantly increased *H. pylori* eradication rates and decreased the adverse effects. We recommend adding 500 mg/day *S. boulardii* concurrently with bismuth quadruple therapy and continuing this therapy for >10 days for optimal *H. pylori* eradication efficacy.

Introduction: Previous studies have suggested an association between *Helicobacter pylori* (HP) infection and osteoporosis. However, the influence of HP eradication on osteoporosis has not been established.

Aims & Methods: The objective of this study was to evaluate whether the risk of developing osteoporosis could be decreased by HP eradication. So, we conducted an observational study of prospectively enrolled cohort. All participants received esophagogastroduodenoscopy with HP tests at the Seoul National University Bundang Hospital from May 2003 to February 2023. HP infection was defined if any one of the following tests was positive: urea breath test, rapid urease test, or histology. Osteoporosis was diagnosed using dual-energy X-ray absorptiometry. The risk of osteoporosis was analyzed using Cox proportional hazard regression analyses.

Results: A total of 8,025 patients were included in the study, and patients under the age of 20, with unknown HP infection status, having a prior history of HP eradication, gastric cancer, or osteoporosis were excluded. Finally, there were 730 patients in the eradicated group and 116 patients in the non-eradicated group. In Cox proportional hazard analyses, the hazard ratio (HR) for osteoporosis in the eradicated group was 0.588 (95% confidence interval [CI] 0.41–0.84, $p=0.003$) referring the non-eradicated group as reference. In addition, multivariate analyses showed that advanced age (HR 1.05, 95% CI 1.03–1.06, $p<0.001$), menopause (HR 3.46, 95% CI 2.25–5.32, $p<0.001$), and history of medicine use (HR 2.86, 95% CI 2.13–3.84, $p<0.001$) were risk factors for osteoporosis (Table).

	Univariate analysis		Multivariate analysis	
	HR (95% CI)	p-value	HR (95% CI)	p-value
HP non-eradicated	Ref.		Ref.	
HP eradicated	0.564 (0.399 – 0.795)	<.001	0.588 (0.413 – 0.836)	0.003
Sex (female)	2.983 (2.018 – 4.411)	<.001		
Age, per year	1.076 (1.061 – 1.091)	<.001	1.046 (1.029 – 1.063)	<.001
BMI, per kg/m ²	0.952 (0.912 – 0.993)	0.023		
Menopause	4.703 (3.387 – 6.532)	<.001	3.457 (2.245 – 5.322)	<.001
*History of medicine use	5.220 (3.966 – 6.871)	<.001	2.861 (2.132 – 3.838)	<.001

Table. Univariate and multivariate analysis of incidence of osteoporosis with *Helicobacter pylori*.

Abbreviations: HR, hazard ratio; CI, confidence interval; HP, *Helicobacter pylori*; BMI, body mass index.

*History of medicine use, patients who have taken any one of denosumab, bisphosphonate, selective estrogen-receptor modulator (SERMs), or hormone replacement therapy (HRT).

Conclusion: The beneficial effect of HP eradication on preventing osteoporosis was observed in this study, even after the adjustment of other confounding factors.

Disclosure: Nothing to disclose.

Introduction: Antibiotic resistance is the leading cause of failure in the eradication of *Helicobacter pylori* (*H. pylori*) infection. In addition to general overuse and misuse of antibiotics, the repetition of the same therapy regimen further promotes the prevalence of resistant *H. pylori* strains. Molecular PCR techniques have enabled clinicians to tailor the treatment according to the antibiotic sensitivity of specific *H. pylori*. For the first time, the Maastricht VI Consensus has made a statement regarding the implementation of PCR.

Aims & Methods: Our aim was to assess the effectiveness of tailored therapy implementation in eradicating *H. pylori* infection evaluating the data from a multicentric, prospective registry of the clinical practice of European gastroenterologists in the management of *H. pylori* infection (Hp-EuReg). All *H. pylori*-infected and PCR-diagnosed patients registered until December 2023 at e-CRF AEG-REDCap were included. Treatment effectiveness was analysed per protocol (accounting only those adherent cases and those with a result either as success or failure to treatment). Effectiveness >85% was considered as satisfactory and >90% as optimal.

Results: A total of 265 patients from XX European countries were tested using the molecular PCR method, 203 (77%) cases on gastric tissue and 62 (23%) on stools. The effectiveness of tailored therapy in treatment-naïve patients was 95%, while the eradication rate in the rescue (from 2nd to 6th) line was 86%. In the first line, the most common prescribed regimens were quadruple-clarithromycin+amoxicillin+metronidazole (C+A+M) therapy, followed by single-capsule quadruple therapy with metronidazole+tetracycline+bismuth (M+T+B), with an eradication rate of 95% and 97%, respectively. In the rescue line, the most common prescribed regimen was

single-capsule quadruple therapy with M+T+B (achieving 87% effectiveness by PP), followed by quadruple C+A+M therapy (94%), triple-amoxicillin+metronidazole (A+M) (93%), and triple levofloxacin+amoxicillin (L+A) therapy (91%) (Table). Clarithromycin and fluoroquinolone resistance rates in the first line were 31% and 33%, respectively; while in rescue line, they were reported higher, that is 63% and 52%; respectively. Table. Most frequent PCR-guided treatments prescriptions and per protocol effectiveness in Europe.

Treatment lines	Patients prescribed (n, %)	Effectiveness (N, %)
First Line		
Quadruple-C+A+M	62, 48%	59, 95%
Single capsule M+T+B	39, 30%	38, 97%
Triple-C+A	7, 5%	7, 100%
Triple-M+A	5, 4%	5, 100%
Rescue line		
Single capsule M+T+B	58, 45%	50, 87%
Quadruple-C+A+M	36, 28%	34, 94%
Triple-M+A	15, 11%	14, 93%
Triple-L+A	11, 8%	10, 91%
C-clarithromycin, A-amoxicillin, M-metronidazole, L-levofloxacin, T-tetracycline, B- bismuth		

Conclusion: PCR-guided tailored therapy showed a consistent optimal (>90%) effectiveness in all therapy lines and prescriptions. This indicates that clarithromycin-based therapy can still be a reasonable treatment choice even in regions with high clarithromycin resistance rate, provided that pretreatment *H. pylori* antibiotic sensitivity is assessed.

PERFORMANCE OF ENDOSCOPIC APPROACHES FOR ZENKER DIVERTICULUM MANAGEMENT: A SYSTEMATIC REVIEW AND META-ANALYSIS

A. Papaefthymioy¹, B. Norton¹, A. Telese¹, K. Siggers¹, M. Duku², A. Murino², G. Johnson², C. Murray², B. Mohammadi², M. Mughal², R. Bisschops³, P. Bhandari⁴, M. Birchall⁵, R.J. Haidry²
¹Cleveland Clinic London, Gastroenterology, London, United Kingdom, ²Portsmouth University Hospitals, Department of Gastroenterology, Portsmouth, United Kingdom, ³Katholieke Universiteit Leuven, Gastroenterology, Leuven, Belgium, ⁴Portsmouth University Hospital, Dept. of Gastroenterology, Portsmouth, United Kingdom, ⁵University College London Hospital, Department of Otolaryngology, London, United Kingdom

Contact E-Mail Address: Andrea.Telese@nhs.net

Introduction: Zenker's diverticulum is associated with a significant burden on quality of life and morbidity, predisposing to dysphagia, regurgitation and aspiration pneumonia. This is often a condition that affects senior patients and access to interventions is limited. Surgery has been the preferred option historically due to a lack of alternative options but remains invasive with major potential complications in an already high-risk patient group. Endoscopic approaches offer a minimally invasive alternative treatment option including rigid and flexible diverticulotomy, and the emerging Zenker per-oral endoscopic myotomy (Z-POEM), albeit no superiority has been demonstrated among these techniques.

Aims & Methods: This systematic review and meta-analysis aimed to summarize the efficacy and safety of these endoscopic techniques. A systematic search in Medline, Cochrane and Scopus databases was performed until November 2023. The primary outcome was technical success, defined as the completion of diverticulotomy/myotomy in one session. Secondary outcomes included clinical success which corresponded to the complete resolution of dysphagia or a post-procedure Dakkak and Bennett score ≤ 1. Moreover, the recurrence rates and the overall adverse events were recorded. Subgroup analyses per outcome were performed to discriminate the results depending on the endoscopic approach (Rigid, flexible diverticulotomy and Z-POEM), whereas the comparative studies were meta-analyzed to compare Z-POEM with alternatives. We used a random effects model and the results were reported as percentages for pooled rates and odds ratios (OR) for comparative data with 95% Confidence Intervals (95%CI).

Results: From 2004 to 2023 twenty-three studies (1357 patients; 40% female; mean age 43-80) were included in our analysis. The cumulative technical success rate was 97.7% (95%CI: 96.9-98.5) with null heterogeneity (I²=0%), and this outcome was preserved in all subgroups. Considering clinical success, the overall pooled rate was 84.8% (95%CI: 80.8-88.8; I²=79.15%) with Z-POEM yielding higher rate [90.4% (95%CI: 87.8-93.1)] with low heterogeneity (I²=11%), in contrast to the alternatives. 8.6% (95%CI: 6.0-11.3; I²: 63.6%) of cases experienced recurrence, with those post-Z-POEM having the lowest rates [5.7% (95%CI: 2.3-9.1; I²:55.68%)] and post-flexible myotomy the highest ones [12.1% (95%CI: 8.0-16.2; I²=36.09%)]. Finally, complications occurred in 8.7% (95%CI: 6.0-11.4; I²=78.08%) with no changes in subgroup analysis. Five studies (759 patients) provided comparative data for Z-POEM and alternatives. Technical success and recurrence rates were similar between comparators [OR:1.38 (95%CI: 0.59-3.23, p=0.5; I²=0%) and OR:0.69 (95%CI: 0.29-1.51, p=0.39; I²=48.71%), respectively], whereas Z-POEM achieved higher clinical success rates [OR:2.38 (95%CI: 1.54-3.68, p<0.001; I²=0%)]

Conclusion: Endoscopic treatment offers high technical success and symptom resolution in patients with Zenker diverticulum, with relatively low prevalence of adverse events and recurrence. Z-POEM offers higher clinical success rates compared to alternatives with optimal homogeneity.

Disclosure: Nothing to disclose.

Introduction: Endoscopic ultrasound (EUS) has emerged as a powerful diagnostic and therapeutic tool in gastroenterology, providing detailed images of the structure's layers, as well as nearby structures. However, EUS is operator-dependent and variability in operator proficiency results in discrepancies in diagnostic accuracy. Artificial intelligence (AI) can be trained to process and interpret EUS images in real-time, potentially mitigating the operator-dependent variability and improving diagnostic accuracy. Moreover, AI can analyze vast datasets offering a level of consistency and efficiency that is challenging for human operators to match.

Aims & Methods: The aim of this study is to compare the diagnostic accuracy of an AI-based model (AIWorks-EUS, mdconsgroup, Guayaquil, Ecuador) against that of expert and nonexpert gastrointestinal endoscopists visual impression in the identification of normal anatomical structures during EUS procedures.

A multi-institutional, cross-sectional, comparative study designed to assess the diagnostic accuracy of the AIWorks-EUS (mdconsgroup, Guayaquil, Ecuador), in identifying normal anatomical structures during EUS procedures compared to that of endoscopists of different expertise. Consecutive patient videos of linear-array EUS were included for analysis. Then, the video dataset was reviewed by 9 endoscopists (5 expert endoscopists and 4 nonexpert endoscopists (<250 EUS procedures), who were blinded to the AI model interpretations. Finally, their visual impression was compared to the observation outputs provided by the AI models.

Results: A total of 29 normal anatomic structures were evaluated by the endoscopists and the AIWorks-EUS software in 39 videos of linear-array EUS. The software reported an observed agreement (OA) of 100% in 15/29 structures (4/9 mediastinal window, 6/12 in gastric window, 5/8 in duode-

nal window). Subcarinal space and portal vein (gastric window) obtained the lowest OA (92.35%). The AIWorks-EUS software obtained a pooled sensitivity, specificity, positive (PPV) and negative predictive value (NPV), and OA for anatomical structure recognition of 95.2%, 99.3%, 97.9%, 98.4%, and 98.2%, respectively. Additionally, the software obtained higher diagnostic accuracy than expert and nonexpert endoscopists ($P < 0.05$). Agreement between endoscopists and the AI per organ evaluated was obtained, with a difference of 18% between the organ with the higher agreement (Aorta) and the lower agreement (Ampulla).

Conclusion: The EUS-based AI model achieved higher diagnostic accuracy than both expert and nonexpert endoscopists in the identification of normal anatomical structures. This model can provide assistance to both groups during live procedures, and studies evaluating its use for training should be conducted to evaluate its application in EUS training programs.

Introduction: Atrophy and intestinal metaplasia (IM) are well-defined preneoplastic conditions and their endoscopic appearance may be subtle. The importance of their identification lies in the fact that it allows the recognition of a high-risk population, enabling an appropriate follow-up.¹ The stigmata of chronic gastritis have been extensively studied and validated with Narrow Band Imaging (NBI) worldwide, while European studies with Blue Light Imaging (BLI) are still limited.^{2,3}

Aims & Methods: The primary aim of this study is to evaluate the applicability of BLI in characterizing chronic gastritis (CG), atrophy and IM comparing it to the gold-standard histology.

All patients undergoing upper digestive endoscopy requiring gastric biopsies, between November 2023 and March 2024, who agreed to participate after written informed consent, were prospectively included. Gastric mucosa was endoscopically evaluated using white light (WL), Linked Colour Imaging (LCI) and BLI, documenting findings and performing biopsies for mapping. Patients with history of gastric surgery were excluded. Statistical analysis was performed using IBM SPSS Statistics version 26®.

Results: A total of 169 patients were included, 55.6% female, with a mean age of 60.2±15.2 years. At the time of the endoscopy, most of the patients had never been tested for *Helicobacter pylori* (74.0%), 12.4% had con-

firmed eradication, 7.1% had previous negative tests and 6.5% had active infection. There was a family history of gastric cancer in 14.2% of patients. Of all endoscopies, 53.8% were performed without any type of sedation. For the evaluation of CG, BLI, LCI and WL were similar (sensitivity = 91.8% vs 92.6% vs 90.2%; specificity = 16.3% vs 14.0% vs 18.6%; positive predictive value (PPV) = 75.7% vs 75.3% vs 75.9%; negative predictive value (NPV) = 41.2% vs 40.0% vs 40.0%; area under ROC curve (AUROC) = 0.54 vs 0.53 vs 0.54, respectively; BLI vs WL *p*-value 0.87; LCI vs WL *p*-value 0.54; BLI vs LCI *p*-value 0.54), as well as for atrophy (sensitivity = 85.9% vs 85.9% vs 84.4%; specificity = 25.7% vs 25.7% vs 31.7%; PPV = 42.3% vs 42.3% vs 43.9%; NPV = 74.3% vs 74.3% vs 76.2%; AUROC = 0.56 vs 0.56 vs 0.58, respectively; BLI vs WL *p*-value 0.17; LCI vs WL *p*-value 0.12; BLI vs LCI *p*-value 1.0). On the other hand, the diagnostic accuracy of BLI was superior to LCI, and both were superior to WL for IM, although at the expense of a higher rate of false positives (sensitivity = 65.9% vs 50.5% vs 34.1%; specificity = 77.2% vs 82.2% vs 85.6%; PPV = 39.5% vs 39.0% vs 34.8%; NPV = 91.0% vs 88.1% vs 85.2%; AUROC = 0.72 vs 0.66 vs 0.60, respectively; BLI vs WL *p*-value <0.001; LCI vs WL *p*-value 0.01; BLI vs LCI *p*-value 0.009). Considering those who underwent endoscopy without any type of sedation, only BLI showed superiority when compared to WL (*p*-value 0.045) but not to LCI (*p*-value 0.41). Also, in this subgroup, LCI was not superior to WL. However, in the subgroup who underwent sedation, the diagnostic accuracy of BLI was even better than the global results (AUROC = 0.79; BLI vs WL *p*-value <0.001; BLI vs LCI *p*-value 0.006). There were eleven visible lesions identified, three of which were detected only with BLI assessment (two with low-grade and one with high-grade dysplasia).

Conclusion: BLI appears to increase the diagnostic accuracy of IM when compared to LCI and WL, and LCI when compared to WL. Regarding the assessment of CG and atrophy, there seems to be an overestimation of findings due to the high rate of false positives. Given the focal nature of IM, sedation is vital for adequate identification and targeted tissue sampling.

ASSESSING THE BENEFIT OF ENDOSCOPIC FOLLOW-UP FOR GASTRIC ULCER AND ASSESSMENT OF A SCORING SYSTEM FOR BENIGN GASTRIC ULCERS

A. Srinivasa¹, S. Wallis¹, S. Booth¹, S. Abdelbadiee¹, N. Yemula¹, A. Subramanian¹, D. Soni¹, E. Plant¹, C. Brew¹, N. Trudgill¹

¹Sandwell and West Birmingham NHS Trust, Gastroenterology, West Bromwich, United Kingdom

Contact E-Mail Address: amarsrinivasa@nhs.net

Introduction: All patients in the UK with a diagnosis of gastric ulcer are recommended to have a follow-up endoscopy within 12 weeks. However, in a low-risk population, such measures may not be necessary. We have assessed a recently developed risk stratification model for gastric ulcers (Brindle Frontline 2022) in a single provider.

Aims & Methods: The aim of this study was to assess the pick up rate of gastric cancer on follow-up endoscopy for patients diagnosed with gastric ulcers and validate a risk stratification model.

A retrospective service evaluation was performed between June 2019 to June 2023 at Sandwell and West Birmingham NHS trust of all patients with an endoscopic diagnosis of gastric ulcer. Patients were followed up until ulcer healing, cancer diagnosis or no further planned follow-up.

Results: 461 patients were studied: median age 63 [interquartile range (IQR) 52-72]; 74% male; and median Charlson comorbidity index 3 (IQR 2-5).

The majority of ulcer diagnoses came from outpatient endoscopy - 69.6%. The ulcer biopsy rate was 64.4% and lower biopsy rates were seen in those who had inpatient endoscopy (41.4%) and therapy (12.1%). The median number of biopsies taken was 4 (IQR 2-5). Additional diagnoses were as follows; gastritis 77%, no additional diagnosis 8%, premalignant lesions 4% (e.g. chronic gastric atrophy) and lymphoma 3%.

Cancer was suspected in 8.7% of ulcers at the initial endoscopy and confirmed histologically in 7%. Cancer diagnoses were in older patients - median age 67 (IQR 59-76) - and all met the urgent two week wait referral criteria for suspected cancer.

Repeat endoscopy for ulcer healing was not done in 32% (reasons included frailty, non-attendance or cancer diagnosis). Two cancers were diagnosed on follow-up endoscopy but both were suspected on index endoscopy - in one the index biopsies did not confirm cancer and in the second no biopsies were taken due to GI bleeding.

Using the risk stratification model proposed by Khalla and Masterton, which required 6 biopsies taken at index endoscopy along with a risk score of less than 3 (consisting of age, ulcer site and ulcer size), 15.6% met the low-risk criteria, where repeat endoscopy may not be required. In that group there were no cancers diagnosed on the second endoscopy.

Conclusion: The risk stratification model appears to perform well suggesting that at least 15.6% of our current endoscopies for gastric ulcer follow-up may not be necessary. Further multi-centre validation of the model is needed.

POST-ENDOSCOPY CARE IN OESOPHAGEAL FOOD BOLUS IMPACTION: INSIGHTS FROM A TERTIARY CENTRE COHORT STUDY

C. Borges Chaves¹, M. Cristiano¹, P. Rocha¹, D. Feijó¹, P. Souto¹, N.P. Almeida^{1,2}, P. Narra Figueiredo^{2,1}

¹Unidade Local de Saúde de Coimbra, Gastroenterology Department, Coimbra, Portugal, ²Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal

Contact E-Mail Address: carlosbchaves123@gmail.com

Introduction: Oesophageal food bolus impaction (FBI) is a frequent emergency in Gastroenterology. Appropriate management involves not only the index endoscopy to resolve the impaction, but also accurate diagnosis and treatment of the underlying oesophageal pathology. If the latter is not achievable during the initial endoscopy, comprehensive follow-up care should be provided. Several recent studies have shown that patients

often do not receive adequate post-endoscopic care after an FBI episode, potentially leading to missed diagnoses of eosinophilic esophagitis and malignancies^{1,2}.

Aims & Methods: The aim of this study was to evaluate the management of patients with FBI and their subsequent follow-up.

A retrospective evaluation of all emergent upper gastrointestinal endoscopies (UGE) conducted at a tertiary centre between November 2019 and December 2023 was performed, including only those with FBI as the indication. Subsequently, follow-up care was assessed. Statistical analysis was conducted using IBM SPSS Statistics version 26®.

Results: A total of 794 patients with FBI were included, with a mean age of 60.3±20.7 years and 41.6% were female. In 19.8% of patients there were previous episodes of FBI, 59.2% of which with a known cause. The majority of food boluses consisted of meat (44.1%), followed by a mixture of foods (26.0%). Most of the times, the FBI episode was solved by carefully pushing the food bolus into the stomach (47.9%). During the index UGE, a probable structural aetiological factor was identified in 38.6% of cases, with Schatzki's ring being the most frequent (19.6%).

However, only 4.4% received appropriate treatment directed toward the cause during the index UGE. Classic findings of eosinophilic oesophagitis were identified in 8.3% of patients, but biopsies were performed in only 30.3% of these cases. Among all patients, only 17.9% underwent endoscopic reevaluation, 5.2±5.6 months after the index UGE, with the aetiology being identified in 77.5% of these.

Globally, the cause of FBI was identified in 42% of cases, known either before, during, or after the index UGE, and only 38.4% of these received treatment. There were 51 cases (6.4%) of diagnosed neoplasia, all known previously or at the index procedure, except for 1 case in a patient not endoscopically reevaluated, and 2 cases reevaluated endoscopically but late (6 and 14 months after FBI).

Conclusion: Most patients did not receive an adequate follow-up plan after index UGE for FBI, albeit a follow-up endoscopy in primary care was proposed in the report. A detailed protocol must be implemented in each endoscopic unit to maintain adequate follow-up and care for patients with FBI.

EFFECT OF BINAURAL BEATS ON ANXIETY AND TOLERANCE IN PATIENTS UNDERGOING UPPER GASTROINTESTINAL ENDOSCOPY WITHOUT SEDATION

F. Sapmaz¹, S. Demirci², S. Sezer²

¹G  lhane Faculty of Medicine, Gastroenterology, Ankara, Turkey, ²Ankara Onkoloji Education and Training Hospital, Gastroenterology, Ankara, Turkey

Contact E-Mail Address: ferda-sapmaz@hotmail.com

Introduction: Binaural beats are perceptual auditory illusions occurring when presenting two similar frequencies to each ear separately, and have been used to reduce anxiety in some procedures. There have been no prior studies involving preprocedure binaural music exposure in patients undergoing upper gastrointestinal endoscopy.

The purpose of this study was to investigate the effect of binaural beats on anxiety and tolerance in patients undergoing sedation-free upper gastrointestinal endoscopy.

Aims & Methods: This prospective randomized controlled trial included 96 Turkish patients aged 18-70 years old scheduled for upper gastrointestinal endoscopy regardless of sex or underlying disease. The patients were randomly divided into two groups: the binaural beat music group (n=48) and the control group (n=48). Those in the binaural music group listened to music using earphones for 15 minutes before endoscopy. No special treatment was given to the control group. The level of anxiety was measured using the State-Trait Anxiety Inventory questionnaire. Hemodynamic changes before and after endoscopy, patient satisfaction based on the number of retches recorded by the physician and tolerance were recorded and compared between the two groups.

Results: STAI state scores were significantly lower after the procedure than before the procedure in the music group, compared to the control group (p=0.016). There were no significant differences between the two groups in terms of systolic and diastolic blood pressure or heart rate changes (p>0.05). Procedure tolerance scores and procedure satisfaction were significantly higher in the music group than in the control group (p>0.05).

Conclusion: In patients undergoing upper gastrointestinal endoscopy, music containing binaural beats was shown to reduce anxiety levels and improve patient tolerance. Music containing binaural beats may be a suitable alternative to sedative medications in patients undergoing gastrointestinal interventions.

Mohammed V – Souissi University. Rabat. Morocco, Hepato-Gastro-Enterology II, Rabat, Morocco

Contact E-Mail Address: reemchaibi46@gmail.com

Introduction: Upper gastrointestinal bleeding (UGIB) is the most common diagnostic and therapeutic emergency in hepato-gastroenterology, potentially life-threatening and requiring multidisciplinary management. Anti-thrombotic (AT) drugs commonly prescribed for cardiovascular diseases are considered a recognised risk factor for UGIB. However, few studies have evaluated their effect on endoscopic outcomes in patients admitted for UGIB, and have concluded that the results remain controversial.

Aims & Methods: Aims: Evaluate the effect of AT use on endoscopic outcomes in patients admitted for UGIB.

Methods: This is a prospective monocentric cross-sectional study of 332 patients conducted between June 2020 and August 2021. We considered as users of AT drugs all patients on antiplatelet agents (low-dose aspirin, thienopyrimidines) and/or anticoagulants (vitamin K antagonists, direct-acting anticoagulants, heparin).

Results: The average age was 59+/-16.7 years. Our series was characterised by a clear male predominance of 77.1%. 63 patients (19%) were taking AT drugs (41 antiplatelet, 39 anticoagulant). The two groups differed in age (68 vs 57; p<0.001), comorbidities (75.8% vs 16.7%; p<0.001), however there was no statistically significant difference in active bleeding at endoscopy (12.7% vs 16.8%; p=0.425), and the need for endoscopic haemostasis (7.9% vs 16%; p=0.1). In multivariate analysis and adjusting for age, sex, comorbidities, presence of active bleeding and use of anti-thrombotics, only the presence of active bleeding could predict the need for endoscopic haemostasis. Indeed, the presence of active bleeding at the time of endoscopy multiplies by 26 the risk of recourse to endoscopic haemostasis (OR: 26, CI: 12.9–62.15, p<0.001), whereas the use of AT drugs does not influence the need for endoscopic haemostasis (OR: 0.386, CI: 0.105–1.42, p=0.154).

Conclusion: Older patients using AT admitted for UGIB do not appear to have an increased risk of active bleeding at endoscopy or needing endoscopic haemostasis.

Disclosure: Nothing to disclose.

MP560

BLEEDING SEVERITY AND TIMING TO ENDOSCOPY: IS THERE ANY EFFECT FOR THE DEATH RISK? A PROSPECTIVE MULTICENTRE COHORT STUDY

C. Marmo¹, C. Buccì², M. Soncini¹, R. Marmo¹, GISED, Gruppo Italiano Studio Emorragia Digestiva

¹Gruppo Italiano Studio Emorragia Digestiva, Rome, Italy, ²Cristina Buccì, Gruppo Italiano Studio Emorragia Digestiva, Rome, Italy

Contact E-Mail Address: clelia.marmo@outlook.it

Introduction: The severity of bleeding and the time-to-endoscopy are generally recognised as risk factors for mortality in patients with GI bleeding. However, how to grade the bleeding severity (BS) is not clearly defined and it is not clear its relationship with the time-to-endoscopy. We found that the bleeding severity correlates with 5 clinical items: altered mental status, systolic blood pressure ≤100 mmHg, blood ureic nitrogen ≥130 mg/dl, haemoglobin ≤8 gr/dl and clinical presentation with hematemesis.

Aims & Methods: The aim of the study is to evaluate if the interaction between bleeding severity and timing-to-endoscopy could impact on the death risk. A prospective multicentre cohort study, including all consecutive patients with upper gastrointestinal bleeding admitted to 50 Italian hospitals was conducted. Charlson's *comorbidity index* and ASA scores were used to define the patients' performance status. According to the previously cited clinical items, we defined bleeding severity (BS) and graded it in low, intermediate, and high-risk classes depending on the presence and the number of items at the time of admission. Timing to endoscopy was defined according to ESGE* guidelines and was divided into 4 time-frames (<6h; 6/12h; 12/24h; >24h).

Weight of risk factors for bleeding severity

Bleeding Severity	Weight
Altered Mental Status	3
Systolic blood pressure ≤100	2
Blood Ureic Nitrogen ≥130 mg/dl	2
Haemoglobin ≤8 gr/dl	2
Hematemesis	1
Max total	10

Results: 2,525 patients were included (mean age 68 [±15.8], male 67.3%); the bleeding was non-variceal in 82.3%. Overall, 176 patients died (6.9%); 28 (1.9%) in the low BS group (1,463 patients), 28 (8.6%) in the intermediate BS group (606 pts) and 96 (21%) in the high BS group (p<0.000). In our population, the 4-time frames do not impact on the mortality in the low and intermediate classes of risk. In the high BS class, there is an interaction between the time to endoscopy and the mortality, with the lower mortality observed in the 6/12 hrs frame.

Conclusion: In our population, the death risk gradually rises as the bleeding severity increases. Bleeding severity identifies 3 different classes of death risk and the time to endoscopy seems unrelated to mortality in low and intermediate BS classes. In the high BS patients, the lower mortality was observed in the timing to endoscopy 6-12 hrs.

SEDATION PRACTICES AND PARADOXICAL REACTIONS IN UPPER GASTROINTESTINAL ENDOSCOPY: AN ONLINE NATIONWIDE SURVEY IN JAPAN

T. Watanabe¹, T. Hirasawa², A. Inaba¹, H. Sunakawa¹, K. Nakajo¹, T. Kadota¹, K. Shinmura¹, T. Yano¹

¹Japan National Cancer Center Hospital East, Gastroenterology and Endoscopy, Kashiwa, Japan, ²Cancer Institute Hospital, Japanese Foundation of Cancer Research., Gastroenterology, Tokyo, Japan

Contact E-Mail Address: takaswat@east.ncc.go.jp

Introduction: Globally, there is no standardized approach to sedation during endoscopic procedures, leading to variability in practices both regionally and across institutions. Sedation plays a crucial role in alleviating patient discomfort and ensuring the safety of endoscopic examinations and treatments.

However, it occasionally leads to paradoxical reaction, which can adversely affect the outcomes of these procedures. As of 2023, in Japan, choice of sedatives and frequency of their use, and the incidence and management of paradoxical reaction during upper gastrointestinal endoscopy remain unclear.

Aims & Methods: This study is aimed to delineate the frequency and types of sedatives used in upper gastrointestinal endoscopy across different medical facilities in Japan and to investigate the extent of anesthesiologist involvement and the incidence and handling of paradoxical reactions. An anonymous online survey was distributed from November 28 to December 13, 2023, through mailing lists reaching about 2,500 gastroenterologists and endoscopists.

Results: The survey received responses from 635 participants including 418 hospital-based endoscopists, 118 clinic-based endoscopists, and screening 29 facility-based endoscopists. Sedation performed by anesthesiologists was found to be rare, with only 3.5% of examinations and 7.1% of treatments being managed by anesthesiologists once a week or more. 87% of respondents reported not using anesthesiologists managed sedation at all for examinations, and 61% reported the same for treatments.

Regarding the frequency of sedation use during examinations, 9.8% of respondents reported using sedation in over 95% of cases, and 53% reported using it in more than half of the cases. 6.6%, reported not using sedation at all. In treatments, 86% of respondents used sedation in over 95% of cases, and 96% used it in more than half of their cases.

Midazolam was the most common sedative for examinations (n=593), chosen in over 80% of cases by 54% of respondents, while only 9.9% never selected it. Meperidine was frequently used by 10% of respondents in similar proportions. Other sedatives like flunitrazepam, diazepam, and propofol were selected by 5.0%, 3.5%, and 2.5% of respondents, respectively.

For treatments (n=401), midazolam was again the most frequently chosen, selected in over 80% of cases by 72% of respondents. Other commonly used sedatives were meperidine and pentazocine, selected in over 80% of cases by 29% of respondents, with propofol and dexmedetomidine each chosen by 12%.

64% of endoscopists who use sedative drugs experienced difficult cases to continue procedures due to paradoxical reactions, with a median incidence of 5% of cases and median of two cases are required to discontinue procedures. Midazolam was the most common cause, reported by 91% of respondents, followed by flunitrazepam (13%), diazepam (8.8%), and propofol (8.3%). The typical response involved physically restraining the patient with multiple staff members' assistance. Eighteen percent of respondents did not use antagonist drugs for examinations, and 22% for treatments.

Conclusion: In Japan, over half of upper gastrointestinal procedures used sedation, with 53% in diagnostics and 96% in treatments predominantly using midazolam. Additionally, 64% of physicians experience difficulties with paradoxical reactions during procedures under sedation by themselves.. These reactions are recognized as significant challenges that must be addressed in the management of sedation for upper gastrointestinal endoscopy.

THE ROLE OF NURSE IN HIGH QUALITY GASTROSCOPY

M. Lupo¹, G.C. Fernicola¹, F. Pigò¹, I. Lolli¹, G.M. De Franco¹

¹Azienda Ospedaliera universitaria di Modena, Gastroenterology and Digestive Endoscopy, Modena, Italy

Contact E-Mail Address: marinella.lupo@gmail.com

Introduction: Digestive Endoscopy services are at third place among hospital services in terms of CO₂ production. In this regard, the European Commission requires a complete reduction of CO₂ emissions by 2050 1-3 . According to the International Agency for cancer research (AIRC) stomach cancer is at 5 th place for incidence and 4th place for mortality 4,5 and these ones have not changed on national scale and they have remained stable since about twenty years. Therefore is necessary an improvement of the endoscopy procedure, that can recognize the risk factors in real time and guarantee more accurate patient care.

Aims & Methods: From April to July 2023 we realized a retrospective control trial enrolling all patients undergoing a gastroscopy added with Endofaster for the evaluation of gastric ph and the presence of H. Pylori.

Results: In a sample of 158 enrolled patients the Endofaster system has demonstrated an accuracy of 79% with a negative predictive value (NPV) of 95%, According to main scientific studies for the diagnosis of atrophic gastritis (AG) and the H. Pylori urease test.

Conclusion: The Endofaster system allows to recognize in real time the alert situations, leading the medical- nursing equipe to the evaluation of the highlighted risk picture, for a best and personalize planning of the diagnostic and therapeutic iter. Furthermore the reduction in biopsy samples leads to a decrease of about 48% in CO₂ emissions per year. 6 Nurses have the opportunity to work alongside and in support of the specialist during an high quality gastroscopy.

Introduction: Crohn's disease (CD) is characterized by significant heterogeneity in phenotypic disease expression, making it challenging to define molecular mechanisms associated with disease and response to therapy. Here we provide a detailed evaluation of the cellular and molecular mode of action of guselkumab (GUS), an IL-23p19 subunit antagonist, in participants with moderately to severely active Crohn's disease (CD) from the GALAXI Phase 2b induction study (NCT03466411).

Aims & Methods: Serum samples were evaluated at baseline, Week (WK) 4 and WK12 for proinflammatory and effector cytokines (serum amyloid A [SAA], CRP, IL-6, IFN γ , IL-22 and IL-17A) from participants treated with intravenous (IV) GUS 200 mg, 600 mg or 1,200 mg induction therapy (n=131 combined) or placebo (PBO) (n=44) who had at least one paired sample at WK0 with WK4 or WK12. A subset of participants from the combined GUS IV induction treatment and PBO groups with a history of stricture or current ileal narrowing were evaluated for collagen-formation (PRO-C3) and degradation (C3M, C4M) serum biomarkers. Baseline biopsies from 241 participants were obtained from rectum (R), splenic flexure (SF), and terminal ileum (TI). Transcriptional profiling was performed with bulk RNA sequencing (RNAseq). An objective tissue-based Molecular Activity Score (MAS) was used to identify inflamed biopsy samples. Inflamed tissue was used to assess regional molecular profiles which were correlated with paired regional histology scores defined by Global Histologic Activity Score (GHAS) and endoscopic severity defined by Simple Endoscopic Score for CD (SES-CD).¹ Transcriptional modules developed using publicly available single cell RNAseq data were then used to assess changes in baseline inflamed tissue associated with specific cellular and immune processes at WK12. Paired biopsies were assessed from the combined GUS IV induction treatment (n=140) and PBO groups (n=51).

Results: Local MAS per region showed highest correlations with paired GHAS from adjacent biopsies (Spearman R 0.72; SF 0.63 and TI 0.70), followed by SES-CD in local segments (R 0.69; TI 0.58). Compared with placebo at WK12, GUS reduced ileum and colon RNA expression levels of IL-17A, IL-22, and IFN γ at Week 12 ($P \leq 0.05$). GUS also significantly decreased cellular processes associated with epithelial inflammation, inflammatory fibroblast and myeloid biology, interferon response and the IL-23 pathway. Regional molecular change was greatest in colon, followed by rectum and ileum. Serum collagen degradation biomarker C4M and the C3M/PRO-C3 ratio demonstrated an association with ileal narrowing and history of stricture at baseline ($P \leq 0.001$). GUS IV induction treatment reduced serum SAA, CRP, and IL-22 as early as WK4 ($P \leq 0.01$) which further declined through WK12 (SAA, CRP, IL-6, IFN γ , IL-22 and IL-17A [$P \leq 0.001$]).

Conclusion: Induction treatment with GUS attenuated key proinflammatory and effector cytokines associated with the IL-23 pathway in CD. Tissue transcriptomics demonstrated attenuation of key immune and inflammatory related processes across all tissue regions compared with PBO. Association of serum collagen degradation biomarkers with ileal

narrowing at baseline provides rationale to further explore the association of differentially expressed genes and transcriptional processes with stricture, fibrosis, and response to treatment.

ACUTE EXPOSURE OF EX VIVO INFLAMED UC AND CD BIOPSIES TO THE SELECTIVE SIK2/SIK3 INHIBITOR GLPG3970 RESULTS IN A STRONG REDUCTION OF PRO-INFLAMMATORY RESPONSES

L. Giorio¹, K. Arnauts¹, M. Colli², E. Vissers¹, B. Verstockt^{1,3}, S. Vermeire^{1,3}, S. De Vos²

¹KU Leuven, Department of Chronic Diseases and Metabolism (CHROMETA), Translational Research Center for Gastrointestinal Disorders (TARGID), Leuven, Belgium, ²Galapagos NV, Mechelen, Belgium, ³KU Leuven, University Hospitals Leuven, Department of Gastroenterology and Hepatology, Leuven, Belgium

Contact E-Mail Address: lorenzo.giorio@kuleuven.be

Introduction: GLPG3970, a potent and selective salt-inducible kinase (SIK) 2/3 inhibitor, exerts a dual mechanism combining anti-inflammatory and immunoregulatory activity.¹ In chronic inflammatory diseases, such as inflammatory bowel disease (IBD), GLPG3970 has the potential to restore immune balance and homeostasis.^{2,3} In a 6-week signal-detection phase 2a study in patients with ulcerative colitis (UC),⁴ GLPG3970 showed

positive effects in histology, endoscopy and faecal calprotectin versus placebo, despite no differentiation from placebo on change from baseline on total Mayo Clinic Score at week 6.^{4,5}

Aims & Methods: We investigated the dual mechanism of GLPG3970 in severely inflamed *ex vivo* treated IBD tissue biopsies. Inflamed intestinal biopsies (most affected segment; n = 9 per patient) were obtained from patients with UC (n = 10) and Crohn's disease (CD; n = 10) with active endoscopic disease (UC: Mayo endoscopic subscore ≥ 2 ; CD: SES-CD of ≥ 4). Patients were biologic-naïve (UC: n = 5; CD: n = 5) or biologic-experienced (UC: n = 5; CD: n = 5). Three individual biopsies per condition were exposed *ex vivo* for 24 hours to vehicle control (DMSO), tofacitinib (10 μ M, positive control) or GLPG3970 (60 μ M). Protein secretion in supernatant was analysed by V-PLEX Human Biomarker 54-Plex (two-way ANOVA, Dunnett's multiple comparison). RNA sequencing of biopsies was performed on Illumina NovaSeq 6000. Gene expression was quantified using Salmon (v1.5.2) and differential expression analysis was performed with DESeq2 (v1.28.0; criteria: $|\log_2FC| > 0.58$, FDR < 0.05, baseMean > 32).

Results: High levels of inflammatory cytokines and chemokines were observed in the supernatant after *ex vivo* culturing. Exposure to GLPG3970 resulted in a significant decrease of pro-inflammatory cytokines (e.g. TNF α , GM-CSF, IFN- γ , IL-2) and chemokines (e.g. MCP-1, MIP1 α , MIP1 β) in both UC and CD biopsies, relative to vehicle control. GLPG3970 activity was statistically stronger than tofacitinib for most evaluated proteins (*p* value), except for IL-1RA, IL-3, IL-9, IL-22, IL-23, among others. RNAseq analysis showed a clear signature of differentially expressed genes (DEGs) for GLPG3970 versus vehicle control (UC: 549 DEGs, with 288 downregulated, including pro-inflammatory genes *CSF2*, *MMP9* and *CCL4*; CD: 673 DEGs, with 238 downregulated, including *CSF2*, *CXCL10* and *CXCL11*). Tofacitinib versus vehicle resulted in 582 (UC) and 681 (CD) DEGs including JAK/STAT dependent genes, such as *MX1*, *SOCS3* and *IFITM1*. Direct comparison of GLPG3970 versus tofacitinib highlighted the impact of GLPG3970 on pathways involved in 'TGF- β signalling', indicative of enhancing immunoregulatory mechanisms, 'TNF α signalling via NF- κ B' and 'glycolysis', whereas tofacitinib mainly affected 'IFN- α response' and 'IFN- γ response' in both UC and CD biopsies. In addition, GLPG3970 exposure to *ex vivo* biopsies resulted in a partial reversion of UC and CD transcriptome signatures (Spearman correlation: -0.25 [UC], -0.22 [CD]).⁶

Conclusion: Acute exposure of GLPG3970 to *ex vivo* inflamed tissue biopsies from patients with UC and CD showed a strong reduction in the release of pro-inflammatory mediators. Transcriptomic analysis further confirmed GLPG3970's robust activity in reducing inflammatory NF- κ B-mediated pathways while modulating TGF- β -related immunoregulatory pathways versus tofacitinib. Our findings support the dual mechanism of GLPG3970 in relevant pathogenic pathways in IBD and confirm the therapeutic potential of SIK2/3 inhibition in treating patients with either UC or CD.

ACTIVATED MACROPHAGE-CONDITIONED MEDIA INDUCES FIBROGENESIS IN A GASTROINTESTINAL SCAR-IN-A-JAR MODEL THAT IS QUANTIFIABLE WITH SEROLOGICAL BIOMARKERS OF COLLAGEN FORMATION

M. Pehrsson¹, F. Gillesberg², Y. Luo³, T. Tsapanou Katranara¹, E.M. Hur³, A.-C. Bay-Jensen¹, S.H. Nielsen¹, S. Khan², M. Sorokina Alexdóttir¹, H.S. Hector¹, J.H. Mortensen¹

Contact E-Mail Address: mpe@nordicbio.com

Introduction: Chronic inflammation in inflammatory bowel disease can lead to the development of intestinal fibrosis, exacerbating the disease. The activation of immune cells results in the release of pro-inflammatory cytokines suspected to drive the activation of fibroblasts and excessive formation of extracellular matrix proteins. While anti-inflammatory therapies exist, their direct effects on fibrogenesis are limited, and model systems for evaluating inflammation-dependent fibrosis are warranted.

Aims & Methods: We aimed to evaluate the profibrotic effects of activated macrophages in a gastrointestinal scar-in-a-jar model by quantifying type I, III, and type VI collagen and fibronectin formation biomarkers.

Macrophages (M ϕ) were isolated from buffy coats from healthy donors and polarized to TNF- α producing M1-like macrophages (M1-M ϕ) using 25 ng/mL IFN- γ and M-CSF over two rounds from days 0 to 6 and from days 7 to 12. The M1-conditioned media was collected on days 6 and 12 (experimental groups: days 0-6 and days 7-12). Colonic fibroblasts (CCD18-Co) were cultured in a crowded pseudo-3D environment using Ficoll (75 mg/mL Ficoll 400 and 112.5 mg/mL Ficoll 70) and supplemented with 50 μ g/mL ascorbic acid to support collagen synthesis. Starting on day 0, exchanging the media every fourth day, the cells were stimulated with 0.3, 3, and 30% of M1 conditioned media, 50 pM TGF- β , or 25 ng/mL IFN- γ and

M-CSF for 12 days, using 3% FBS as the control. The biomarkers PRO-C1, PRO-C3, PRO-C6, and FBN-C, quantifying type I, III, and VI collagen formation and fibronectin, were measured in the supernatants on days 0, 4, 8, and 12. The metabolic activity of the cells was assessed on days 0 and 12 using an Alamar Blue assay. The statistical differences in biomarker levels were calculated using the area under the curve (AUC) compared with the unstimulated FBS control applying Brown-Forsythe and Welch or one-way ANOVA tests.

Results: Quantified using the PRO-C1, PRO-C3, PRO-C6, and FBN-C biomarkers stimulation with 30% M1-Mφ media from days 0-6 and 7-12 resulted in a switch in collagen formation compared to the FBS control, reducing type I collagen and fibronectin and increasing type III and VI collagen formation (Table 1). A similar response was observed using 3% of 0.3% M1-Mφ media, though to a lesser degree (Table 1). The data suggest increased pathological fibroblast activity and fibrotic deposition of type III and VI collagen formation driven by Mφ-derived cytokines. TGF-β, a known profibrotic cytokine, induced a significant formation of type I, III, VI, and fibronectin compared to the FBS control (Table 1), demonstrating a different fibrotic biomarker profile than Mφ induced fibrosis. IFN-γ+M-CSF stimulation, used for Mφ activation, inhibited the formation of type III collagen (Table 1).

Stimulation	PRO-C1 (p-value)	PRO-C3 (p-value)	PRO-C6 (p-value)	FBN-C (p-value)
30% M1-Mφ (days 0-6/days 7-12)	Decreased: p<0.05 / p<0.05	Increased: p<0.01 / p<0.0001	Increased: p<0.01 / p<0.0001	Increased: ns / p<0.01
3% M1-Mφ (days 0-6/days 7-12)	Decreased: p<0.05 / ns	Increased: ns / p<0.01	Increased: ns / p<0.001	Increased: ns / p<0.05
0.3% M1-Mφ (days 0-6/days 7-12)	ns	Increased: ns / p<0.05	ns	Increased: ns / p<0.05
TGF-β	Increased: p<0.0001	Increased: p<0.01	Increased: p<0.0001	Increased: p<0.0001
IFN-γ+M-CSF	ns	Decreased: p<0.0001	ns	ns

Calculation of statistical differences was done between the specific stimulation and the unstimulated FBS control applying Brown-Forsythe and Welch or one-way ANOVA tests. For each biomarker a notation of „Increased or Decreased“ is applied to indicate the numerical change compared to the FBS control. P-values < 0.05 was deemed a significant change. Abbreviations: ns, non-significant

Table 1: Overview of the statistical differences in the PRO-C1, PRO-C3, PRO-C6, and FBN-C biomarkers between the stimulated and unstimulated FBS control.

Conclusion: Stimulating colonic fibroblasts with conditioned media from activated macrophages induced a profibrotic response with increased type III and type VI collagen formation. The applied serological biomarkers enabled the objective quantification of collagen and fibronectin formation to assess fibrogenesis in the model and their potential use for investigating macrophage induced fibrosis.

A NEW APPROACH TO MOLECULAR DIAGNOSTICS AND STAGING OF ULCERATIVE COLITIS

A. Iakovlev¹, G. Tarasova¹, A. Volkov¹, O. Bastovaya¹, A. Zubova¹, V. Piscovets¹
¹Rostov State Medical University, Gastroenterology, Rostov-on-Don, Russian Federation

Contact E-Mail Address: gastroklinika@yandex.ru

Introduction: The molecular pathways for the development of ulcerative colitis (UC) are unclear. The purpose of the work is to study the molecular interactions of the apoptotic pathway in patients with UC.

Aims & Methods: The study was prospective comparative cohort with parallel design and included 65 patients (range from 22 to 35 years, 24 men and 41 women) with left-sided UC, mild and moderate activity (True-love - Witts' criteria, Mayo score). The induction of UC remission assumed the acceptance of mesalazine 3 to 4 g/day p.o. and rectally 1 to 2 g/day, the duration of therapy was 4.6 years. The control group included 30 healthy individuals. The separation of individual proteins of colon mucosa was based on technologies of IEF, SDS-PAGE, 2DPAGE, by standard sets (MB-HIC C8 Kit, MB-IMAC Cu, MB-Wax Kit, «Bruker», USA). Automated mass spectrometry imaging was performed by matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF-MS/MS, Ultraflex II, «Bruker», USA). The partially identified sequences were then submitted to “BLAST protein-protein” and screened against the Homo sapiens Swissprot database to check if this identification matched the MASCOT-identification (Matrix Science, UK). The data of the molecular interactions and functional features of proteins were received with STRING 10.0 database. Based on the data of standard methods of identification of UC and molecular phenotyping of colon mucosa we conducted new prognostic markers, molecular pathways of UC and diagnostic tests in patients with UC. Statistical analysis of the survey data was performed using the software “Statistica 12.0” (Statsoft).

Results: Bioinformatics analysis revealed the presence of molecules that are the participants in the universal pathways of UC in the active stage, and the molecular interactions involved. We identified following functional groups of peptides and proteins in molecular patterns of biotates of colon mucosa in UC patients: peptides and proteins regulating the barrier function of colon mucosa; proteins-participants of specific metabolism in epitheliocytes and endocrinocytes; proteins of the fibrosis in colon mucosa; proteins regulating cell cycle, oncogenesis, proteolysis in cell, hormones processing, angiogenesis, coagulation factors; proteins of free radical oxidation and antioxidant system; proteins regulating the receptor activity of epitheliocytes and immune cells; structural proteins of colon mucosa; transcription and translation factors regulating the activity of cell nucleus, regulators of protein folding; transport proteins; proteins-enzymes of detoxification. Significant decrease of the PPARγ expression promotes the activation of STAT and AP-1 signaling pathways, which promotes an increase in the synthesis of IL-2,6,8,12, TNFα, matrix metalloproteinases, the activity of immune and inflammation processes in colon mucosa. A significant increase in the NF-κB expression in colon mucosa is associated with the activation of TNFα and IL-1, which promotes the increase of immune processes in colon mucosa. The molecular interactions of β-defensin-1: the reduction of the β-defensin-1 expression in cells of colon mucosa is accompanied by increased expression of CCR6, which promotes the formation of inflammatory infiltrates in colon submucosa in UC.

Conclusion: Identification of potential new molecular markers for UC development may provide opportunities for the development of diagnostic tests to evaluate the disease.

Disclosure: Nothing to disclose.

DISCOVERY AND CHARACTERIZATION OF A NOVEL HIGH-AFFINITY ANTI-TL1A MONOCLONAL ANTIBODY WITH EXTENDED HALF-LIFE FOR THE TREATMENT OF INFLAMMATORY BOWEL DISEASE

Introduction: Tumor necrosis factor (TNF)-like ligand 1A (TL1A) mediates a broad spectrum of pro-inflammatory and fibrotic effects and has been genetically linked to multiple immunologic disorders. In clinical trials, antagonist antibodies that interfere with the interaction between TL1A and Death Receptor 3 (DR3) reduce disease activity in ulcerative colitis (UC) and Crohn's disease (CD).

Here, we provide data on a novel human IgG1 effector-less monoclonal antibody (mAb) that incorporates the Xtend™ half-life extension technology. This antibody binds soluble and cell surface-expressed TL1A with high affinity and selectivity and potently inhibits TL1A-DR3 mediated signaling.

Aims & Methods: Over 1000 anti-TL1A antibodies were screened in binding and/or functional assays. Select clinical candidate antibodies were further compared to clinical-stage anti-TL1A mAbs PRA023/MK-7240/tulisokibart, RVT-3101/RG6631, and TEV-48574. Binding affinity of the lead antibodies to soluble TL1A was determined by surface plasmon resonance (SPR). Binding to cell plasma membrane-expressed TL1A was confirmed by flow cytometry (FACS). Competitive inhibition of TL1A binding to DR3 and its decoy receptor DcR3 was determined by ELISA and biolayer interferometry. Inhibition of TL1A binding to plasma membrane-expressed DR3 was evaluated using FACS.

Antibody antagonism of cellular DR3 signaling by exogenous TL1A was evaluated through assessment of TF-1 cell apoptosis and interferon γ (IFN γ) secretion from CD4⁺ T cells. Lead antibodies incorporating the Xtend™ Fc domain (M428L/N434S substitutions) to improve half-life were evaluated in pharmacokinetic studies using human FcRn knock-in mice and non-human primates.

Results: The clinical candidate anti-TL1A antibodies bind with high affinity and specificity to trimeric TL1A and not to the related TNF ligand superfamily members LIGHT, TRAIL and FasL. The lead antibodies demonstrate an apparent K_D of less than 20 pM for soluble TL1A at 37°C and bind to TL1A over-expressed on the cell plasma membrane. Further, these antibodies potently inhibit TL1A-induced apoptosis of TF-1 cells, and IFN γ secretion from human CD4⁺ T cells - all with IC₅₀ values comparable to those of RG6631 and lower than those of tulisokibart. Lead antibodies demonstrate an improved serum half-life in human FcRn knock-in mice relative to the non-half-life extended RG6631.

In preliminary non-human primate studies, the clinical candidate antibodies demonstrate half-lives greater than 20 days, with the expected antibody-TL1A complex formation. Allometric scaling using parameters adjusted for half-life engineered antibodies predict human half-lives of 70 days or higher, potentially enabling dosing intervals of Q8wk or longer. Preliminary formulation development supports a high concentration, citrate-free formulation above 150 mg/mL, suitable for subcutaneous administration.

Conclusion: The clinical candidate antibodies bind with high affinity and specificity to TL1A and demonstrate potent blockade of TL1A-mediated DR3 receptor signaling. In human FcRn knock-in mice and in cynomolgus monkeys, these antibodies show an extended half-life consistent with FDA-approved antibodies using the Xtend™ technology. These data demonstrate the therapeutic potential of the clinical candidate antibodies in the treatment of TL1A-mediated diseases such as ulcerative colitis and Crohn's disease - with the advantage of infrequent subcutaneous dosing.

Introduction: Viral infections targeting the intestinal epithelium are a significant cause of gastroenteritis, leading to decreased nutrient and electrolyte absorption. Despite supportive care, the lack of effective treatment options necessitates exploration of various alternatives, with probiotics being among them. Probiotics, live microorganisms with demonstrated health benefits, have emerged as a potential solution due to their ability to interfere with viral replication and modulate immune responses. The use of intestinal organoids in research has highlighted the advantages, particularly in mimicking the innate immune response and allowing for the study of host-specific interactions.

Aims & Methods: Building upon *in vivo* evidence of probiotics' antiviral activity, this study aims to investigate their immunomodulatory effects on primary human intestinal epithelial cells derived from organoids. Intestinal organoids were established from the non-inflamed ileal and colonic mucosa of Crohn's disease and Ulcerative colitis patients. Organoid-derived monolayers were generated and used to evaluate the anti-viral effect of *L. rhamnosus* GG® and *B. animalis* ssp. *lactis* BB-12. Differentiated intestinal epithelial monolayers were exposed to the probiotic strains with multiplicity of infection (MOI) 1:10 for 3 hours, and following extensive washing incubated for additional 24 hours in complete medium containing antibiotics. The expression of viral recognition genes (*IFIH1*, *TLR3*, *TLR7*, *TLR9*), antiviral response signaling pathway genes (*IRF3*, *IRF7*, *MAVS*), antiviral cytokines (Type I IFN) genes (*IFNA1*, *IFNB1*), Type I IFN signaling pathway genes (*STAT1*, *STAT2*) and Interferon Stimulated Genes (*EIF2AK2*, *IFITM1*, *IFITM2*, *IFITM3*, *OAS1*, *MX1*) was assessed by Real Time RT-PCR.

Results: Exposure to both *L. rhamnosus* GG® and *B. animalis* ssp. *lactis* BB-12 significantly increased the expression of the antiviral cytokine *IFNB* in ileum-derived monolayers but not in colon-derived monolayers compared to untreated controls. Moreover, *B. animalis* ssp. *lactis* BB-12, but not *L. rhamnosus* GG®, significantly induced the expression of *OAS1*, a gene involved in the inhibition of viral replication, in both ileum and colon-derived monolayers compared to untreated controls.

Conclusion: Preliminary findings suggest that certain probiotic strains may elicit robust antiviral responses, presenting a promising avenue for the prevention and management of viral gastroenteritis.

Introduction: Inflammatory bowel disease (IBD) and irritable bowel syndrome (IBS) represent chronic and occasionally disabling conditions, necessitating innovative treatment strategies. Covering 14% of Ireland's landscape, bogland ecosystems house unique plant biodiversity, yielding biologically active secondary metabolites.

Informed by traditional medicinal knowledge and in vitro screening for immunomodulatory potential, three plant extracts (NTP0226A, NTP0127B, NTP0206EA) were selected for exploration of their potential to treat IBD and IBS within the "Unlocking Nature's Pharmacy from Bogland Species" project.

Aims & Methods: Patients undergoing colonoscopy were prospectively recruited in three cohorts: healthy controls, IBS, and ulcerative colitis (UC). Recto-sigmoid biopsies were collected. Ex-vivo colonic tissue explants were generated and cultured for 24 hours with treatments (Infliximab, NTP0226A, NTP0127B, NTP0206EA). Real-time energy metabolism profiles and secretion of 10 inflammatory mediators were assessed using Seahorse Xfe24 analyser and multiplex ELISA, respectively. Levels of macrophage polarisation following exposure to treated explants were analysed by flow cytometry. Total protein content allowed result normalization, with significance set at $P < 0.05$.

Results: Twenty-seven patients were recruited (6 healthy controls, 6 IBS, and 15 UC). UC patient explants exhibited elevated glycolytic metabolism and increased IL-4, IL-6, and IL-12p70 secretion compared to non-UC patients. No differences were observed between healthy controls and IBS patients. Linear regression did not show difference between age and mitochondrial bioenergetics. There was no change in metabolism profiles of any cohort following treatment with Infliximab or the 3 novel extracts. In the UC tissue, treatment with Infliximab reduced IL-12p70 secretion ($p=0.0098$), this reduction was not seen in the other 2 cohorts. NTP0206EA reduced IL-10 secretion in the UC cohort ($p=0.0255$). In the IBS cohort; NTP0127B reduced IL-10 secretion ($p=0.0048$) and NTP0226A reduced IL-4 ($p=0.004$) and IL-6 ($p=0.0219$) secretion. Macrophages exposed to UC explants treated with infliximab showed a reduction in HLA-DR, CD54 and CD163 and an increase in TIM-3 and CD206 expression ($p<0.05$). Macrophages exposed to UC explants treated with NTP0206EA showed reduced CD163/CD206 expression ($p<0.05$). NTP0226A and NTP0127B did not alter macrophage polarisation. Principal components analysis demonstrated reduced separation between the immune-metabolic profiles of UC patients and healthy controls following treatment with NTP0226A.

Conclusion: Using an explant model, we have shown that UC patients have a distinct immune-metabolic profile modifiable by a standard IBD therapy and novel plant extracts. Blockade of IL-6 trans-signalling has recently shown promise as an effective treatment target in IBD. Our natural extract NTP0226A reduced IL-6 secretion in IBS patients and is a promising candidate for therapeutic exploration. These findings contribute to our understanding of the complex interplay in the colonic microenvironment and highlight potential avenues for novel therapeutic interventions.

Introduction: Fibrostenosis represents one of the major clinical complications of Crohn's Disease (CD). However, the molecular mechanisms underlying intestinal fibrogenesis remain poorly understood and anti-fibrotic therapy has not yet been developed. Growing evidence supports that oxidative stress and the epithelial-mesenchymal transition (EMT) process contribute to the development and progression of fibrosis.

Aims & Methods: Based on these evidences, we assessed the role of lipids in fibrogenesis and whether mitochondria dysfunction can support fibrosis formation.

Spatial metabolomics analysis and adipophilin (ADFP) staining were performed on surgical specimens from fibrotic ileum and the surrounding region (healthy) derived from CD patients. Fibroblasts isolated from fibrotic and healthy ileum and human induced pluripotent stem cell-derived intestinal organoids (iHOs) were treated for 1-3 weeks with lipid mix (2%) and analyzed by RNA sequencing. Pathways significantly modulated were validated by RT-PCR, WB, FACS analysis, and proliferative, migratory and contraction assays, and mitochondrial functions by Seahorse analyzer.

Results: Spatial metabolomics revealed a significant accumulation of lipids characterized by very long-chain fatty acids in the fibrotic area compared to surrounding healthy regions, which was further confirmed by ADFP staining. RNA-seq analysis showed overlapping dysregulated pathways between healthy fibroblasts stimulated with lipids and fibrotic fibroblasts, in particular genes related to cell cycle, cytoskeletal reorganization, migration, contractility and cell metabolism (oxidative stress) which were further confirmed by functional assays. Among the genes re-

lated to oxidative stress, lipid stimulation significantly decreased *NFE2L2* and promoted an increase in *CPT1A*, gene encoding for a fatty oxidation mediator.

Moreover, lipid-stimulated fibroblasts showed a reduction in mitochondrial respiration, particularly basal and maximal respiration, and spare respiratory capacity by Seahorse analysis. On the other hand, long exposure of iHOs to lipids promoted the EMT process through the upregulation of *TWIST*, *ZEB*, and *VIM*.

Conclusion: Lipid stimulation induced myofibroblast activation through oxidative stress and alteration of mitochondrial metabolism, and increased the expression of EMT transcription factors in intestinal epithelial cells (iHOs) that may support fibroblast-mediated pro-fibrotic activity. These data indicate that regulators of fatty acid oxidation involved in the fibrotic process may represent new potential targets for the treatment of fibrostenotic CD patients.

Introduction: The interleukin 36 (IL-36) family includes the agonists IL-36 α , IL-36 β , IL-36 γ , which activate the NF- κ B pathway and the natural antagonist IL-36RA, which inhibits IL-36 signaling. While missense mutations in the gene encoding IL-36RA (*IL36RN*) are associated with severe skin inflammation, their role in Crohn's disease (CD) is currently unknown. Therefore, we here investigated if *IL36RN* mutations contribute to inflammation in CD and whether IL-36 signaling might represent a potential drug target for personalized therapy.

Aims & Methods: Mutations in *IL36RN* were identified by whole exome sequencing (WES) followed by targeted Sanger sequencing. Peripheral blood mononuclear cells (PBMCs) of affected patients were analyzed by mass cytometry and serum cytokines were measured by ELISA. Identified *IL36RN* mutations were characterized by overexpression experiments and functional assays. Clinical and molecular responses of one *IL-36RN* mutant patient to combined treatment with spesolimab and certolizumab pegol was assessed by fecal calprotectin, endoscopy and mass cytometry at week 0 and 12 of treatment.

Results: In a cohort of 86 ulcerative colitis patients, 244 CD patients and 45 healthy controls, we identified 4 CD patients with heterozygous missense mutations in *IL36RN* (IL-36RA S113L, IL-36RA P76L and IL-36RA L133I). In the patient carrying the IL-36RA S113L variant, we detected elevated serum levels of IL-18 and IL-23, as well as an increased frequency of TH17 cells in PBMCs, suggesting an overactivation of the IL-36 pathway. Overexpression experiments showed that IL-36RA S113L causes decreased expression of IL-36RA, resulting in increased IL-36 signaling. The patient was therefore treated with 1200 mg of the IL-36R blocking antibody spe-

solimab every 4 weeks and 200 mg of certolizumab pegol biweekly on the basis of an Out Of Scope request. This approach resulted in reduced intestinal inflammation and a reduction in the frequency of pro-inflammatory myeloid cells in PBMCs.

Conclusion: In this study, we show that pathogenic *IL36RN* mutations are present in a subset of CD patients and that blocking IL-36 signaling may represent a personalized therapeutic approach for this rare subset of patients in whom conventional biologic therapies have failed.

Introduction: Late onset neonatal sepsis (LOS) is a leading cause of mortality in preterm infants, affecting up to 15% of preterm neonates and a mortality rate of ~15%¹. Clinical symptoms of LOS are nonspecific and the diagnosis is therefore often established in an advanced stage of infection, negatively impacting prognosis, illustrating the need for novel preclinical biomarkers².

This study aimed to identify predictive biomarkers for LOS in preterm infants using faecal metagenomics and targeted metabolomics. Functional implication of identified biomarker on preterm neonatal barrier function was assessed in foetal intestinal organoid models.

Aims & Methods: In a Dutch multicentre study, including 9 neonatal intensive care units, faecal samples and clinical data were collected daily from birth to onset of *S. aureus* and *E. coli* LOS in preterm neonates (<30wks gestation) and matched to healthy controls by gestational and postnatal age, mode of birth, antibiotics exposure and birth centre (n=10 *E. coli*, n=10 *S. aureus*). 16S sequencing and shotgun metagenomics was performed to characterise fecal microbiota, as well as targeted HPLC MS/MS to determine tryptophan (Trp) metabolites of serotonin, kynurenine and indole pathway up to 7 days before LOS diagnosis.

In vitro effect of Indole-3-aldehyde (I3A) and heat inactivated culture medium (CDM) of *E. coli* clinical isolates was assessed human foetal intestinal organoid models. Tight junction and AhR expression was determined in 3D organoids by RTqPCR on TJP-2, CLDN-1,-4,-10, OCLN, AHR and CYP1A1. Exposed 2D organoid monolayers were assessed by longitudinal trans epithelial electrical resistance (TEER) and wound healing assay³. Consecutively, effect of I3A on intestinal barrier function during infection with *E. coli* clinical isolate was assessed by barrier translocation and longitudinal TEER⁴.

Results: The metagenomic faecal relative abundance of *E. coli* was significantly higher 4-5 days before onset of clinical symptoms of *E. coli* LOS, compared to matched controls (P=0.045, 95% CI cont. -0.47-1.72%, LOS = 17.21-101.3%). In contrast, no significant difference in abundance of faecal *S. aureus* was detected in neonates prior to *S. aureus* LOS. Further analysis indicated altered genetic abundance of Trp related genes in the *E. coli* LOS metagenome 4-5 days prior to LOS diagnosis. Of detected me-

tabolites, Tryptamine was significantly decreased (adj.P=0.03), Indole (adj.P=0.002), Indole-3-sulfate (adj.P=0.02) and I3A (adj.P <0.0001) were significantly elevated prior to *E. coli* LOS.

3D fetal intestinal organoid experiments showed significantly increased CYP1A1 expression in organoids exposed to I3A at concentration measured in faeces (100µM). A trend of increased tight junction expression was observed, indicating potential effect of I3A on intestinal barrier prior to LOS. TEER measurements showed increased barrier resistance and decreased proliferation of I3A exposed 2D organoids.

Additionally, infection of I3A exposed organoid monolayers with clinically isolated *E. coli* showed indication of more rapid and increased barrier disruption.

Conclusion: This research indicates an increase in faecal relative abundance of *E. coli*, but not of *S. aureus* prior to LOS onset, and a functional difference mediated by Trp metabolism and microbially produced I3A. *In vitro* analysis of I3A effect on barrier integrity, proliferation and *E. coli* infection suggest altered barrier function preceding LOS. These results indicate relevance of I3A as novel preclinical biomarker as well as a functional metabolite potentially influencing the preterm intestinal barrier.

HOST AND MICROBIAL TRYPTOPHAN METABOLISM IN IRRITABLE BOWEL SYNDROME: RELATION TO ORO-ANAL TRANSIT TIME AND SYMPTOMS

C. Moretti¹, K. Sjöberg Jabbar¹, H. Törnblom¹, T. van Gils¹, W. Sjöland¹, J. Algera¹, V. Tremaroli¹, F. Bäckhed¹, M. Simrén¹

¹University of Gothenburg, Institute of Medicine, Department of Molecular and Clinical Medicine, Sahlgrenska Academy, Gothenburg, Sweden

Introduction: The pathophysiology of irritable bowel syndrome (IBS) includes alterations in gut-brain communication, gastrointestinal (GI) physiology and gut microbiota. The essential amino acid tryptophan (Trp) is metabolized in the gut to different classes of metabolites, including serotonin, kynurenine and indoles which have been implicated in the modulation of intestinal motility, immune function and pain sensation.

Balanced Trp metabolism requires a complex host-microbiota interplay, which might be dysregulated in IBS. However, Trp metabolism is incompletely understood, and studies are needed to clarify its link with IBS and gastrointestinal physiology.

Aims & Methods: Aim: To profile fecal and circulating levels of Trp metabolites in IBS and explore relationships with oro-anal transit time (OATT) and symptoms.

Methods: We combined targeted and untargeted metabolomics to determine fecal and serum Trp metabolites in a cohort of healthy controls (HC; n=29) and IBS patients with predominant constipation (IBS-C; n=59), diarrhea (IBS-D; n=53) or mixed bowel habits (IBS-M; n=55). OATT was measured using radiopaque markers and participants completed questionnaires to assess GI symptom severity (GSRS-IBS), stool frequency and consistency (Bristol Stool Form Scale), non-GI somatic symptoms (PHQ-12), and symptoms of anxiety and depression (HAD). For correlation analyses, Spearman's rho (r) was used.

Results: Levels of Trp did not differ significantly between HC and IBS subtypes. The Trp metabolite kynurenine, the microbially produced indole propionic acid (IPA) and the serotonin degradation metabolite 5-hydroxy-indoleacetic acid (5-HIAA) were lower in IBS-C compared to HC and IBS-D. There were inverse correlations between OATT and both fecal ($p < 0.0001$; $r = -0.40$) and circulating ($p = 0.021$; $r = -0.17$) Trp levels. Similarly, stool kynurenine and indoles were negatively correlated with OATT. Fecal but not circulating serotonin was positively correlated with OATT ($p = 0.041$; $r = 0.14$) while 5-HIAA showed a negative correlation ($p < 0.0001$; $r = -0.29$), suggesting potential serotonin accumulation due to deficient degradation. In IBS patients, fecal Trp, 5-HIAA, IPA and kynurenine, correlated negatively with the proportion of hard stools (BSF1-2) and positively with the proportion of loose stools (BSF6-7). Finally, serotonin catabolites and IPA were negatively correlated with the severity of constipation and positively correlated with diarrhea. No statistically significant correlations were noted between these metabolites and abdominal pain, abdominal distension, early satiety, or postprandial fullness while bloating was positively correlated with circulating IPA ($p = 0.018$; $r = 0.18$). Additionally, we report a negative correlation between circulating serotonin with symptoms of depression and anxiety, which was not found for fecal serotonin. No significant correlations were noted with non-GI somatic symptoms.

Conclusion: Our results suggest that slower transit time may favour increased intestinal catabolism of Trp, directly or indirectly through its effects on the gut environment and the microbiota. In addition, we report an association of fecal Trp metabolites with bowel habits, in line with their relations to OATT. On the other hand, these same fecal metabolites did not correlate with other GI (i.e., pain and bloating) or non-GI symptoms. This study underscores the link between intestinal transit time and the regulation of host and microbial metabolites important for intestinal homeostasis.

Introduction: Inflammatory bowel disease (IBD) shows significant variations in clinical presentation, prevalence, and epidemiology across the world. We hypothesized that these differences might be, in part, due to regional variations in gut microbiomes. To test this, we examined gut microbiota of IBD patients and healthy controls in Northern part of India, and compared our findings to Dutch patients and population.

Aims & Methods: We collected stool samples and clinical metadata from 226 IBD patients (198 ulcerative colitis, 28 Crohn's disease) and 66 controls in Northern India. Metagenomic shotgun sequencing was employed to assess gut microbiota diversity, composition, and function. Associations between microbiome profiles and IBD subtypes, along with clinical parameters like medication usage, drug response, and disease activity, were investigated. We compared our findings to a Dutch cohort comprising 436 IBD patients and 903 controls, using a consistent analytical approach. Finally, we used machine learning approaches to evaluate the generalizability of Indian IBD signals to the Dutch population.

Results: Indian IBD patients exhibited reduced microbiome diversity and alterations in beta diversity ($FDR < 0.05$, replicated in the Dutch cohort). We identified 319 taxa and 71 biochemical pathways significantly altered in Indian patients ($FDR < 0.05$), with 39% of these signals replicated in the Dutch cohort (at $FDR < 0.05$). Shared dysbiosis patterns across Indian and Dutch IBD patients included expansion of opportunistic pathogens (e.g., *Clostridium*, *Streptococcus*, *Lactobacilli* genera) and oral bacteria (e.g., *Streptococcus oralis*, *Bifidobacterium dentium*), alongside reduction in butyrate producers (e.g., *Faecalibacteria*, *Roseburia hominis*, *Blautia massiliensis*). Furthermore, we identified unique pathobionts specific to the Indian cohort, including *Scardovia* and *Oribacterium* genera, *Actinomyces dentalis* and *Klebsiella pneumoniae*. Machine learning models trained on the Indian cohort exhibited high predictive accuracy within the Indian test set (Sensitivity 0.84, Specificity 0.95) and demonstrated generalizability to the Dutch cohort (Sensitivity 0.77, Specificity 0.69). Additionally, we found associations between medication use and gut microbiota independent of disease activity: Tofacitinib usage (by 26 UC patients) correlated with decreased *Lactobacilliales* and increased *Clostridia*, while Prednisolone and Azathioprine usage associated with reduced *Roseburia* and increased *Streptococcus* and *Granulicatella*.

Conclusion: IBD patients from Northern India exhibit gut dysbiosis patterns similar to European patients, alongside enrichment in India-specific pathobionts. Microbiome-based diagnostic models show generalizability across populations, demonstrating the potential utility of microbiota-based approaches in IBD diagnosis and management across diverse populations.

Introduction: Gut micorbiota in patients with cystic fibrosis (pwCF) is severely disrupted and a potential source of further complications. We aim to provide quantitative evidence of the differences in gut microbiota between pwCF and non-CF controls to understand CF gut flora composition and identify potential sites for microbiota modulation with special focus on time-dependent changes.

Aims & Methods: We conducted a systematic review and meta-analysis of PubMed, EMBASE, CENTRAL, Web of Science, and Scopus up to November 13, 2023 (CRD42023482792). Included were case-control studies assessing gut microbial alpha diversity or relative abundance in pwCF and controls without gut-affecting conditions or drugs. Standardized mean differences (SMD) with 95% confidence intervals (CI) were calculated using a random-effects model for both outcomes. We performed subgroup analysis for alpha diversity for infants, children, and adults. We used the Joanna Briggs Institute risk of bias tool.

Results: Among 2550 studies, 11 met inclusion criteria (enrolling 1174 subjects). Alpha diversity analysis showed age-specific changes. Observed OTUs were non-significantly decreased in adult pwCF compared to controls (SMD=-1.57; 95%CI -4.21 to 1.08, across 3 studies, 80 pwCF and 100 controls).

Children with CF displayed a significantly reduced Shannon index (SMD=-1.43; 95%CI -2.06 to -0.79, across 3 studies, 77 pwCF and 78 controls). However, in infants, no difference was detected in Shannon index between CF patients and controls (SMD=0.05; 95%CI -0.74 to 0.84, across 4 studies, 288 pwCF, 519 controls).

Analysis of follow-up data in infants revealed a decreasing tendency of Shannon index in pwCF compared to controls during the first year of life (SMD=0.67; 95%CI -1.20 to 2.54 at 4 months vs. SMD=0.45; 95%CI -1.81 to 2.71 at 6 months vs. SMD=-0.61; 95%CI -1.98 to 0.75 at 12 months).

A significant increase in the relative abundance of Veillonella and E.coli marked the CF group with a noticeable increase of Enterobacter and decrease of Bacteroides and Faecalibacterium compared to controls (see Table).

Taxon name	No of studies	No of pwCF and controls	Level of taxonomic order	Standardised mean difference	Confidence interval (95%)	Heterogeneity
Actinobacteria	4	219/93	Phylum	-0.12	-1.04 – 0.80	69%
Bacteroides	4	96/512	Genus	-0.53	-2.04 – 0.98	93%
Blautia	4	96/512	Genus	-0.14	-0.51 – 0.24	0%
Enterobacter	3	255/461	Genus	0.32	-0.11 – 0.76	0%
Enterococcus	4	96/512	Genus	0.07	-0.70 – 0.83	70%
Faecalibacterium	3	75/103	Genus	-0.32	-2.01 – 1.37	83%
Streptococcus	4	96/512	Genus	0.16	-0.79 – 1.11	79%
Veillonella	4	96/512	Genus	0.97	0.04 – 1.90	78%
E.coli	4	213/107	Species	0.65	0.10 – 1.20	33%

Conclusion: Gut microbial alpha diversity is reduced in adults and children with CF compared to controls, while infants with CF exhibit similar diversity, which continuously decreases during the first year of life. Perturbations in the intestinal microbial ecosystem are defined by a significant

increase in E.coli and Veillonella abundances within individuals with CF compared to controls enabling specifically targeted microbiota modulation.

Introduction: Gut pathogens play a relevant role in shaping the natural history of noncommunicable chronic gastrointestinal (GI) disorders, as they are not only a risk factor for the development of irritable bowel syndrome (IBS) and inflammatory bowel diseases (IBD)^{1,2}, but can also trigger a clinical relapse of these conditions². Molecular testing for quick pathogen detection have been made available in recent years, but their sensitivity may result in clinically insignificant positive findings, as gut pathogens may be present, at low counts, also in clinically healthy individuals³. Their use is also recommended in stool donor screening flowchart to minimize the risk of transmission of infectious diseases during fecal microbiota transplantation (FMT).

Aims & Methods: Our aim was to evaluate whether the presence of gut pathogens, assessed by a direct molecular stool testing, differs in different GI disorders and healthy individuals. In this retrospective study, we evaluated the results of a commercially available, RT-PCR-based molecular stool testing for the detection and identification of 25 common gut pathogens (RT-PCR Allplex™ Gastrointestinal Panel Assays, Seegene, Seoul, Korea) in three different cohorts, including: patients with IBD; patients with IBS; candidate stool donors of our FMT centre. Testing were required when common microbiological stool testing (i.e. stool culture, C. difficile toxin, parasitological assays) were negative. We collected the following data of recruited individuals: age, gender, presence of GI symptoms (assessed with the GSRS) and disease activity (assessed with PMS, HBI).

Results: Overall, 403 stool tests were retrospectively analyzed. Of them, 177 came from 46 healthy donors (n= 89 tests of females, mean age 44; range: 21-69; SD 12.5); 183 from 146 patients with IBD (n=100 tests of females, mean age 40.4; range: 16-82; SD 16.2), and 27 from 26 patients with IBS (n= 12 tests of females, mean age 39; range: 16-68; SD 17.1). Among healthy donors, 60 (34%) tests were positive, 15 (8%) for multiple species. Enteropathogenic Escherichia coli (EPEC) was the most frequently isolated strain (n=23; 13%). In the IBD cohort, 155 tests were collected in patients with active disease, and among them 59 (38%) tests turned out to be positive, 18 (12%) for multiple species, with EPEC being the most common strain (n=15; 10%), followed by Aeromonas spp (n=13; 8%), Blastocystis hominis (n=11; 7%) and Clostridium difficile (n= 10; 6%). In this cohort, 28 tests were also requested to patients under quiescent disease, and 10 (36%) were positive. In patients with IBS, all tests were conducted during active, symptomatic phases of disease (IBS-D: n=19, 68%; IBS-C: n=8; 30%), with 13 (48%) positive testing, mainly due to Blastocystis hominis (n=5; 19%), followed by Dientamoeba (n=3; 11%), and by multiple species in 11% of patients (n=3).

Conclusion: In our cohort, the positivity rates of gut pathogens at direct molecular stool testing were similar among healthy donors (34%), patients with active (38%) and quiescent (36%) IBD, being slightly higher in patients with active IBS (48%). Based on these preliminary finding, direct molecular stool testing, in absence of positive stool cultures, is associated with asymptomatic colonization from gut pathogens, rather than with clinically relevant infections, both in healthy controls and in patients with noncommunicable chronic GI disorders.

Introduction: H. pylori eradication therapy induces significant alterations in the gut microbiome. While probiotics have been extensively studied as a potential strategy to mitigate microbiota-related consequences of antibiotics, their efficacy remains a subject of debate.

Aims & Methods: The aim of our study was to evaluate the influence of butyric acid+inulin supplements on gut microbiota changes (including gut microbiota taxonomic composition, functional potential, and gut resitome) induced by H.pylori eradication therapy.

A total of 22 H. pylori-positive patients aged 19 to 64 years were enrolled in the study. Patients were randomized into two H. pylori eradication regimens: 1) ECAB-14: esomeprazole 20 mg, clarithromycin 500 mg, amoxicillin 1000 mg, and bismuthate tripotassium dicitrate 240 mg, twice daily, orally, for 14 days. 2) ECAB-Z-14: esomeprazole 20 mg, clarithromycin 500 mg, amoxicillin 1000 mg, and bismuthate tripotassium dicitrate 240 mg, twice daily, along with butyric acid+inulin (Zacofalk) supplementation (two tablets daily, each containing 250 mg of butyric acid and 250 mg of

inulin), orally, for 14 days. Stool samples were collected from each subject at three time points: prior to eradication therapy (I), after therapy completion (II), and one month post-therapy (III). Total DNA from fecal samples was isolated for whole genome sequencing using the Illumina NextSeq 500 platform.

Results: Gut Microbiota Alpha Diversity (Shannon Index): Immediately after eradication therapy, both the ECAB-14 and ECAB-Z-14 groups experienced a significant decrease in gut microbiota alpha diversity compared to the initial level: (2.46 ± 1.06) vs. (3.75 ± 0.342), p = 0.0029, and (3.22 ± 0.73) vs. (3.82 ± 0.30), p = 0.037, respectively. After one month, the Shannon index was restored to the baseline level in the ECAB-Z-14 treatment group: no statistically significant differences were identified between time points III and I [(3.71 ± 0.33) vs. (3.82 ± 0.30), p = 0.206]. However, even a month after therapy, the ECAB-14 treatment group still exhibited a lower Shannon index than the baseline level [(3.27 ± 0.39) vs. (3.75 ± 0.342), p = 0.019].

Functional Potential Alterations: In the ECAB-Z-14 treatment group, less pronounced alterations in gut microbiota functional potential were observed. Specifically, 72 metabolic pathways changed immediately after eradication therapy. In contrast, the ECAB-14 group showed impact on 112 signaling pathways.

Butyrate Production Genes: The abundance of genes associated with butyrate production decreased only in the ECAB-14 treatment group. However, in the ECAB-Z-14 treatment group, the abundance of genes responsible for butyrate production remained stable.

Antibiotic Resistance Genes: The prevalence of gut microbiota antibiotic resistance genes increased significantly in both treatment groups immediately after eradication. Notably, more severe alterations were observed in the ECAB-14 treatment group, where the abundance of 73 antibiotic resistance genes significantly increased. Meanwhile, the ECAB-Z-14 group showed an increase in only 50 antibiotic resistance genes immediately after eradication therapy.

Conclusion: H. pylori eradication therapy significantly affects gut microbiota composition, functional potential, and increases the abundance of antibiotic resistance genes. However, the addition of butyric acid+inulin supplements to the H. pylori eradication regime may mitigate these effects.

Disclosure: Nothing to disclose.

ANTIDEPRESSANT TREATMENT OF IBS: ACTION OF A HERBAL ANTIDEPRESSANT, ST. JOHN'S WORT EXTRACT, ON GUT MICROBIOTA

M.E. Grafakou¹, E.-M. Pferschy-Wenzig¹, H. Aziz-Kalbhenn², O. Kelber², R. Bauer¹

¹University of Graz, Institute of Pharmaceutical Sciences, Department of Pharmacognosy, University of Graz, Graz, Austria., Graz, Austria, ²Steigerwald Arzneimittelwerk GmbH, Phytomedicines Supply and Development Center, Bayer Consumer Health, Darmstadt, Germany

Contact E-Mail Address: maria.grafakou@uni-graz.at

Introduction: Antidepressants are an integral part of the treatment of IBS as a disorder of gut-brain interaction (DGBI). Accordingly also a direct interaction with the gut microbiota might be relevant as an additional mode of action. With its high content of flavonoids, a substance group for which beneficial neuromodulatory effects, mediated by the microbiota, are known. St. John's wort extract, an antidepressant with clinically proven therapeutic equivalence to TCAs and SSRIs, could be a promising candidate for such an additional action, also as there is a history of use also in GI complaints.

Aims & Methods: Aim was to follow the test substance, a St. John's wort extract (STW 3-VI), with clinically proven anti-depressant activity [1] and standardized flavonoid content [2], through the GI tract. According to the Infogest protocol [3,4], first the influence of the upper GI digestion on the extract was modelled by subsequent incubation with respective enzymes and buffer mixes. The predigested extract was subsequently incubated with fecal samples from ten healthy donors (24h, anoxic, 37°C). The metabolism of the flavonoids by the gut microbiota was captured by UHPLC-HRMS, and also proteolytic markers (BCFA and ammonium) were measured by GC-FID and IPB colorimetric analysis. 16S rRNA gene sequencing was used to assess shifts in microbial community composition, followed by functional analysis via ATLAS, using KEGG, Cazy and Pfam for annotations.

Results: All major extract constituents were stable towards upper intestinal tract digestion. They were, however, readily catabolized by the gut microbiota. Metabolites of the flavonoids included taxifolin, hydroxy-phenylpropionic acids and protocatechuic acid. Proteolytic markers were significantly decreased. Differential abundance analysis of the microbial communities showed that several taxa were significantly modulated by the extract, with e.g. Bacteroides ($p=0.005$) Marinifilaceae ($p=0.0007$) and Prevotellaceae ($p=0.035$) decreasing. Functional analysis revealed 540 differently expressed genes ($p<0.01$), some involved in flavonoid metabolism.

Conclusion: Beyond the known antidepressant activity of St. John's wort extract, its components are also prodrugs for substances with potential therapeutic benefits in IBS as well as in psychic depression [5]. This is in accordance to the results of the functional analysis of the gut microbiota, given that changes of abundance of bacterial taxa by the treatment antagonize abundance shifts described in depressive as well as IBS patients [6]. The decrease of proteolytic markers is also in line with a beneficial action in IBS [7]. In conclusion, St. John's wort might, beyond its known efficacy in mild to moderate depression, also be a promising therapeutic option in IBS patients, especially with co-occurring depressive symptoms.

ASSESSING AWARENESS AND ATTITUDES TOWARDS FECAL MICROBIOTA TRANSPLANTATION (FMT) IN ARMENIA: A STUDY AMONG MEDICAL STUDENTS, HEALTHCARE PROFESSIONALS, AND PATIENTS

S. Grigoryan¹, I. Navoyan¹, A. Hazoyan¹, A. Gabrielyan¹, M. Grigoryan¹, G. Matsakyan¹, A. Khalatyan², M. Gemilyan¹

¹Yerevan State medical University, Gastroenterology and Hepatology, Yerevan, Armenia, ²Mikayelyan Institute of Surgery, GI Endoscopy, Yerevan, Armenia

Contact E-Mail Address: Sofyagrigoryan13@gmail.com

Introduction: Fecal Microbiota Transplantation (FMT) stands as a promising therapeutic approach for gastrointestinal disorders, notably recurrent *Clostridioides difficile* infection. Despite its potential, the awareness and perceptions surrounding FMT among stakeholders in low and middle-income countries, such as Armenia, remain relatively unexplored.

Aims & Methods: This study aimed to assess awareness and attitudes towards FMT among 4th to 6th-year medical students of Yerevan State Medical University (YSMU), healthcare professionals at Mikayelyan University Hospital, and patients of the same hospital in Armenia. The primary aim is to evaluate awareness and attitudes towards FMT among these groups and, as a conclusion, to increase awareness among the Armenian population, both patients and physicians, and to promote the integration of microbiota-based researches and therapeutic methods in Armenia. **Methods:** A questionnaire-based study was conducted among 143 medical students from YSMU (Yerevan State Medical University), 56 healthcare professionals (including gastroenterologists, infectious disease specialists, internists, and endoscopists) at Mikayelyan University Hospital, and 82 patients undergoing outpatient and inpatient treatment at the same hospital. Participants were surveyed to gauge their awareness level, perceptions, and willingness regarding FMT.

Results: This study explores the intricate landscape of awareness and attitudes towards Fecal Microbiota Transplantation (FMT) among medical students, healthcare professionals, and hospital patients in Armenia. Delving into their perspectives, this research offers nuanced insights into the reception and readiness for FMT adoption. Among surveyed medical students, university education emerged as the predominant source of knowledge (47.5%), while 43.4% recognized FMT's efficacy in treating *Clostridium difficile* infection, with notable percentages acknowledging its potential for inflammatory bowel disease (37.3%) and irritable bowel syndrome (12.0%). Among healthcare professionals, insights revealed that conferences/seminars (41.4%) and scientific journals/publications (37.5%) played pivotal roles in information dissemination, with a striking 72.1% recognizing FMT's effectiveness against *Clostridium difficile* infection. However, challenges such as the lack of clear guidelines (40.3%) and limited donor material availability (25.8%) underscored existing barriers to FMT application. Patient perspectives offered invaluable insights, with 12.5% exhibiting prior awareness of FMT, prompting further exploration into their readiness and reservations. Post-information dissemination, 33.8% expressed a newfound readiness for FMT application, highlighting the pivotal role of education in shaping patient attitudes. Noteworthy concerns among patients included apprehensions regarding the procedure's unpleasantness (52.2%) and the perceived lack of evidence (13.0%). Furthermore, preferred delivery methods, such as oral capsules (70.6%) and colonoscopy (23.5%), shed light on patient preferences and comfort levels.

Conclusion: The study highlights a significant knowledge gap regarding Fecal Microbiota Transplantation (FMT) among medical students, doctors, and patients in Armenia. Specifically, 44.1% of students, 21.4% of doctors, and 83.3% of patients had never heard of FMT. Despite this initial lack of awareness, 33.8% of patients expressed willingness to undergo FMT after

receiving explanations. This underscores the potential for education and awareness-raising initiatives to positively impact attitudes towards FMT adoption in Armenia.

Disclosure: Nothing to disclose.

STUDY OF THE EFFECT OF FECAL MICROBIOTA TRANSPLANT THAWING TIME ON THE TREATMENT EFFECT OF RECURRENT CLOSTRIDIODES DIFFICILE INFECTION

J.B. Shin¹, B. Cha¹, J. Hong¹, K.-S. Kwon¹

¹Inha University Hospital, Gastroenterology, Incheon, South Korea

Contact E-Mail Address: shinjongv@naver.com

Introduction: Fecal microbiota transplantation (FMT) is most effective treatment for recurrent *clostridioides difficile* infection (rCDI). Some factors associated with donor, recipients and FMT protocols (amount of feces, infusion route, number of infusion, time of thaw) affect FMT outcome. However, the appropriate FMT protocol is still being studied, and research on the most effective thawing time is lacking.

Aims & Methods: The purpose of this study was to optimize the effect of thawing time of frozen FMT stool on rCDI.

This prospective, single center and randomized controlled trial was performed from October 2022 to December 2023. Patients were randomly assigned to groups that received stool for FMT thawed 4 hours at room temperature (4HTG) or thawed 12 hours in a refrigerator (12HTG). Stools were donated from single healthy donor. Each donation was diluted in glycerol-saline solution (12.5% glycerol in 0.90% w/v NaCl in water) and thoroughly homogenized. A 250 mL formulation containing 60g of stool was stored at -80 °C and administered via colonoscopy within 4 months. The primary outcome was the cumulative recurrence rate of *Clostridioides difficile*-associated diarrhea (CDAD) at week 8. The CDAD resolution rate at 1 week, adverse events related to thawing time were also evaluated.

Results: Total of 22 patients were randomized into 4HTG (n=12) vs 12HTG (n=10). CDAD resolution was achieved in all patients regardless of thawing time (100% vs 100%, p<0.001). On the other hand, the cumulative recurrence rate was significantly lower in 4HTG compared to 12HTG. (0% vs 30%, p=0.045). The observed species, Chao1, and Shannon indices for alpha-diversity measures revealed that there was greater microbial richness among groups in the post FMT group than in the pre FMT group. (p<0.001) A comparison of gut microbiota composition was performed using PCoA based on beta diversity of unweighted UniFrac distances. The 4HT group was found to be more similar to the donor than the 12HT group.

Conclusion: This study demonstrated that thawing time did not affect CDAD resolution but did make a difference in recurrence rate. This is the first study to show that the thawing time of frozen stools affects the CDAD recurrence rate and that 4-hour room temperature thawing should be preferred.

MH002, AN OPTIMIZED LIVE BIOTHERAPEUTIC PRODUCT, FOR THE TREATMENT OF INFLAMMATORY BOWEL DISEASES, HAS MODE-OF-ACTIONS LINKED TO RESTORATION OF INTESTINAL DYSBIOSIS, MUCOSAL INTEGRITY, AND IMMUNE HOMEOSTASIS

S. Bolca¹, M. Doynova¹, M. de Leeuw¹, I. Pinheiro¹, K. Conrath¹, S. Possemiers¹, L. Haazen¹, S. Vermeire²

¹MRM Health NV, Zwijnaarde, Belgium, ²University Hospital Leuven, Dept. of Gastroenterology, Leuven, Belgium

Contact E-Mail Address: selin.bolca@mrmhealth.com

Introduction: Treatment options for patients with mild-to-moderate ulcerative colitis (UC) failing 5-ASA are limited. MH002 is an optimized live biotherapeutic product consisting of 6 non-pathogenic, well-characterized commensal bacteria. Its anticipated mechanism in UC is reversion of dysregulated host inflammatory mechanisms and interactions with gut microbiota, and induction of mucosal healing.

Aims & Methods: In this 2:1-randomized, double-blind, placebo-controlled first-in-disease study (EudraCT 2020-001355-33), 45 patients with mild-to-moderate active UC (Modified Mayo Score [MMS] =4-8 and centrally assessed Mayo Endoscopic Sub-score [MES] ≥2) received treatment with 400mg MH002 or placebo (PBO) once daily for 8wks, followed by an 8-wk extension with MH002 (same dose) unless responding to PBO. All patients were on stable 5-ASA for ≥4wks prior and during the study. Full colonoscopies with biopsies were performed at baseline and wk8. The primary endpoint was the rate of treatment-emergent adverse events. Exploratory efficacy endpoints included clinical remission (MMS≤2 with all sub-scores ≤1 and rectal bleeding =0), endoscopic improvement (MES≤1), clinical response (reduction of MMS of ≥3 points or a reduction of ≥1 point of the Mayo sub-scores for stool frequency and rectal bleeding), biomarker normalisation, and mechanistic effects of MH002. Here, changes in faecal microbiome (shotgun metagenomics) and gene expression of colonic mucosal biopsies (whole transcriptome RNAseq) are reported.

Results: MH002 treatment was safe and well tolerated, and resulted in clinically meaningful improvements in disease activity and inflammatory parameters¹. At wk8, endoscopic improvement was achieved in 6/28 (21%) and 2/14 (14%) patients treated with MH002 and PBO, respectively. In this MH002-treated subgroup, α-diversity (Pielou evenness, Shannon diversity) increased significantly as compared to baseline whereas the relative abundance of Enterobacterales decreased significantly over time (1-sided Wilcoxon p<0.05). Similar but less pronounced changes were observed in MH002-treated patients achieving clinical response or even no response. Furthermore, a total of 1496 significantly differentially expressed genes (DEGs) at wk8 vs. baseline were found in the MH002-treated patients with endoscopic improvement (p<0.05; lnFC>1.5). Among the most significantly downregulated DEGs are the regenerating islet-derived (REG) genes (REG1α, REG1β, REG3α) and serum amyloid A (SAA) genes (SAA1, SAA2, SAA4). Since REG proteins have bactericidal, anti-inflammatory, and tissue repair functions, and SAA are acute-phase proteins induced by inflammatory stimuli, this could result from a state of lower inflammation and activation by bacterial components, from the resolution of tissue injury, and from lower local gut inflammation following treatment. Lastly, when intersecting these DEGs with UC-associated DEGs reported in 3 independent studies^{2,3}, 16-21% of intersecting DEGs showed fold changes in opposite polarity to UC vs. healthy individuals whereas 0-3% showed similar fold changes.

Conclusion: These observations suggest that MH002-treated patients had positive changes in gut microbial diversity and overall microbiome composition, coinciding with clinical improvement and downregulation of genes involved in immune and inflammatory responses, antimicrobial defense mechanisms, and resulting in dampening of immune cells' activi-

ty, and associated with UC. MH002, therefore, represents a promising new treatment for mild-to-moderate UC patients insufficiently controlled with 5-ASA. These results warrant further development in a phase 2/3 study.

Introduction: Statins and anti-inflammatory non-steroidal drugs (NSAIDs) like aspirin have already been demonstrated to reduce the risk of developing PDAC. Whether there is a beneficial effect of these drugs in patients with established PDAC is poorly investigated.

Aims & Methods: Our aim is to investigate the association between the use of aspirin, statins, angiotensin-converting-enzyme (ACE) inhibitors and sartans and the clinical outcome in a prospective cohort of PDAC patients.

Single-centre prospective cohort of consecutive PDAC patients, with baseline demographics, exposome and pharmacological data, details on tumour features, treatment (chemotherapy/surgery) and survival recorded. The effect of the investigated drugs on overall survival was investigated by Kaplan-Meier curves and multivariate analysis using a Cox proportional hazards regression model. Tests of statistical significance and confidence intervals were two-sided; a value of $p < 0.05$ was considered statistically significant.

Results: 419 patients with histologically diagnosed PDAC were included, mean age 67, 51.7% male; 50 (11.9%) stage I, 152 (36.2%) stage II, 110 (26.2%) stage III, 107 (25.5%) stage IV; 368 patients (87.8%) underwent chemotherapy as first treatment, of whom 304 (82.6%) polychemotherapy (PAXG, FOLFIRINOX or gemcitabine plus nab-paclitaxel); 129 patients (30.7%) underwent surgical resection, most after chemotherapy. Ninety-four patients (22.4%) aspirin users, 101 (24.1%) statin users, 72 (17.1%) ACE inhibitors users, 91 (21.7%) sartans users. Median estimated OS was 20 months with 228 patients (54.4%) dead at last follow-up. In the whole cohort Kaplan Meier survival analysis showed a longer OS in statin users vs non users (21 vs 18 months). At Cox regression use of statins (HR 0.69; $p=0.02$ (0.506-0.952 95% CI)), age (HR 1.046 (1.030-1.062 95% CI), $p<0.0001$) and stage (HR 1.466 (1.280-1.679 95% CI), $p<0.0001$) had a significant impact on OS. In subgroup analyses of patients with resectable patients (stage I and II) and advanced stages (III and IV) there was no significant effect. All the other investigated drugs were not significantly associated with OS.

Conclusion: The present results suggest that chronic use of statins is significantly associated with increased OS in patients affected by PDAC at Cox proportional hazard regression. Whether this beneficial effect is due to less indolent tumours or better response to treatments require further investigation.

Introduction: The incidence of Early Onset Pancreatic Cancer (EOPC), which is defined as PC diagnosed before the age of 50 years, seems to be rising in recent years. It has been suggested that EOPC may differ from Late Onset Pancreatic Cancer (LOPC) in terms of biology, genetic expression, and tumour behaviour. Our aim was to retrospectively analyze EOPC cases diagnosed at our institute to have a better insight into the PC disease when it affects young patients.

Aims & Methods: This is a retrospective cohort study: pathological reports from pancreatic EUS-biopsy or transabdominal liver biopsies were collected. Demographic data, risk factors exposure (smoke, alcohol intake, BMI), oncologic familiar history as well as genetic tests, stage at diagnosis and follow-up data were collected.

Results: We found 49 cases of EOPC diagnosed at our institute since 2015. Twenty-seven on 49 patients were male (55%); mean age at diagnosis was 45.9 years old; mean BMI was 22.37. Sixteen on 49 (32 %) patients were metastatic at the diagnosis. Twenty-two patients were tested on a genetic panel of 26 genes (18 genes before 2023) associated with PC and 9 (18%) patients had a positive test for a high penetrance pathogenetic variant (PGVs). Eighteen on 49 (37 %) patients had positive familiar oncologic history (mostly pancreatic, breast, and ovarian cancers).

Conclusion: Based on our data, we would conclude that there is a significant association between EOPC and high penetrance PGVs. A consistent number of cases are diagnosed in metastatic stage, which means we should invest on prevention and early diagnosis, especially for high-risk population such as for patients with positive familiar oncologic history. Our aim for the future is to create a prospectively maintained and multi-centre registry of EOPC.

Disclosure: Nothing to disclose.

Introduction: Chronic pancreatitis (CP), influenced by both genetic and environmental factors, poses a significant health burden with its progressive nature. While excessive alcohol consumption is a prominent risk factor, non-alcoholic chronic pancreatitis (NACP) presents challenges due to less overt precipitating factors.

Aims & Methods: We aimed to assess the impact of rs7057398 and rs12688220 variants at the *RIPPLY1-CLDN2-MORC4* locus and rare functionally deficient *TRPV6* variants in NACP susceptibility.

Systematic search was conducted on PubMed, Embase, and Web of Science databases on November 2, 2023, aiming to assess non-alcoholic acute recurrent pancreatitis (ARP) and CP cases, excluding conference abstracts and preprints. The protocol was prospectively registered (CRD42023438777). Utilizing a random-effect model with REML estimation, odds ratios (OR) with 95% confidence intervals (CI) were computed using the allelic model (rs7057398: C vs T; rs12688220: T vs C) for the total population and hemizygotes as well, the homozygote (rs7057398: CC vs TT; rs12688220: TT vs CC) and heterozygote model (rs7057398: CT vs TT; rs12688220: TC vs CC). Minor allele frequency (MAF) was calculated for both variants. In the analysis of functionally deficient rare *TRPV6* variants were collectively pooled and compared to cases without mutations affecting *TRPV6* function, calculating OR with 95% CI. Subgroup analysis, stratified by age, set the threshold for early-onset CP at 30 years in all cases. Statistical heterogeneity was evaluated using Chi² tests and I² values. Due to limited study numbers, funnel plots and Egger's test were deemed inappropriate. Risk of bias was assessed using the Joanna Briggs Institute's tool.

Results: Six studies were included in the quantitative analyses for SNPs rs7057398 and rs12688220. MAF for rs7057398 was 0.49 (CI 0.31 to 0.67) in cases and 0.38 (CI 0.27 to 0.50) in controls. For rs12688220, MAF was 0.46 (CI 0.27 to 0.67) in cases compared to 0.35 (CI 0.24 to 0.47) in controls. MAF was notably higher in Indian and Asian studies compared to European cohorts. Both risk alleles were significantly associated with NACP in homozygotes, heterozygotes and hemizygotes, respectively (see Table).

SNP	Model	Cohorts	Cases	Controls	OR	95% CI	I ² [95% CI]
rs7057398	Allelic	6	1424 / 3049	2884 / 8803	1.54	1.17; 2.01	75% [44;89]
	Homozygote	6	200 / 506	361 / 1830	2.22	1.12; 4.42	63% [10;85]
	Hemizygote	6	577 / 1153	935 / 2689	1.52	1.14; 2.03	51% [0;80]
	Heterozygote	6	447 / 753	1227 / 2696	1.64	1.36; 1.98	0% [0;75]
rs12688220	Allelic	6	1589 / 3396	3418 / 10405	1.64	1.10; 2.45	92% [85;96]
	Homozygote	5	146 / 502**	287 / 1834**	1.87	1.31; 2.66	30% [0;71]
	Hemizygote	5	497 / 1333**	807 / 3275**	1.53	1.07; 2.17	69% [28;87]
	Heterozygote	5	367 / 723	1131 / 1678	1.36	1.07; 1.73	0% [0;79]

In the allelic model, minor allele carriers displayed significantly increased odds for NACP for rs7057398 (OR 1.54, CI 1.17 to 2.01, p=0.009) and rs12688220 (OR 1.64, CI: 1.10 to 2.45, p=0.025). Limited data was available on early-onset cases, therefore definitive conclusions cannot be drawn. Functionally deficient *TRPV6* variants were associated with a 35-fold increased odds of developing NACP compared to individuals without these

variants (OR = 35.32, CI 20.72 to 60.22, across 4 cohorts, 2236 cases and 2748 controls). Risk of bias was generally judged to be high in the included studies.

Conclusion: Our meta-analysis highlights the significant association of variants rs7057398 and rs12688220 of the *RIPPLY1-CLDN2-MORC4* locus, along with functionally deficient *TRPV6* variants, with NACP. These findings emphasize the importance of genetic screening for identifying individuals at risk of NACP and inform personalized intervention strategies.

Introduction: Pancreatic cancer (PC) diagnosis may be preceded by acute pancreatitis (AP) in up to 14% of cases. Although follow-up imaging is recommended in AP with unclear etiology, the particularities of the PC cases associated with AP are still to be defined.

Aims & Methods: The aim of our study was to characterize the subgroup of PC cases preceded by AP.

We included in the analysis all patients referred to our tertiary center for endoscopic ultrasound guided tissue acquisition and subsequently confirmed diagnosis of pancreatic adenocarcinoma (PAC) between January 2019 and December 2023. We cases with and without AP prior to PAC diagnosis. Continuous variables are reported as mean ± standard deviation (SD) or median and range. Categorical variables are reported as rates (%). To compare the groups, we used 2 tailed Fisher's exact and independent samples t test. Subsequent multivariate analysis was to identify the characteristics of the AP prior PAC subgroup.

Results: Our cohort comprised 144 patients, aged 68 (40-86), with almost equal sex distribution (55% males). 48% were metastatic at diagnosis, and there was a slight predominance of proximal tumor location (57% - head/uncinate process lesions). AP preceded PAC in 9% of cases. These patients were younger (61.54±10.45 vs. 67.08±8.19, P=.035), more frequently smokers (84 vs. 44%, P=.007), had mostly proximal lesions (84 vs. 55% - head/uncinate process located tumors, P=.015) and pain at diagnosis (100 vs. 73%, P=.044). There was no association between AP prior PC and sex, alcohol consumption, diabetes, obesity, tumor size, vascular invasion or metastatic stage. Smoking (OR 5.92; 95%CI 1.18-29.59) and proximal tumor location (OR 5.57; 95%CI 1.13-27.58) were independently associated with AP prior PAC.

Conclusion: Although small, our cohort study revealed that AP precedes PAC in younger patients and smokers. The increased inflammatory response occurring at younger age may favor the carcinogenesis while smoking is a risk factor for recurrent AP and chronic pancreatitis. Association with proximal tumor location probably results from the obstructive AP pathomechanism in these cases.

Disclosure: Nothing to disclose.

Introduction: Pancreatic cancer has remained one of the most serious malignancies and is still a leading cause of cancer-related deaths worldwide. Great attention has been paid to the relationship between diabetes mellitus and pancreatic cancer. At the time of diagnosis of pancreatic cancer, impaired glucose metabolism has been reported to be present in variable rates according to particular studies (ref.).

Aims & Methods: Aims: The aim of our study was to analyse mutual association of pancreatic cancer and diabetes mellitus in the whole population of the Czech Republic within a 5-year period.

Methods: Based on the individual population data from the Czech National Cancer Registry, the incidence of pancreatic cancer in 2017-2021 was estimated. Another data source, the National Registry of Reimbursed Health Services that collects data from health insurance companies, was used to estimate people recently diagnosed with diabetes mellitus. For the purpose of this study, diagnosis of new-onset of diabetes mellitus was defined as the time of the first prescription of any antidiabetic drug (subgroup of patients with prediabetes treated with metformin was included). Patients with diabetes treated with diet only were not included. Subsequently, people diagnosed with pancreatic cancer in 2021 were retrospectively followed up to see if they had been diagnosed with diabetes mellitus in the last 5 years (or earlier) before diagnosis of pancreatic cancer.

Time of diagnosis of diabetes mellitus (DM)	Age: 39 years and younger	Age: 40-59-year old	Age: 60-74-year old	Age: 75 years and older	TOTAL
DM diagnosed within 1 year prior to cancer diagnosis	0 (0.0%)	29 (9.4%)	82 (7.1%)	54 (5.9%)	165 (6.9%)
DM diagnosed within 2 years prior to cancer diagnosis	1 (5.6%)	5 (1.6%)	44 (3.8%)	11 (1.2%)	61 (2.6%)
DM diagnosed within 3 years prior to cancer diagnosis	1 (5.6%)	5 (1.6%)	33 (2.9%)	27 (3.0%)	66 (2.8%)
DM diagnosed within 4 years prior to cancer diagnosis	0 (0.0%)	5 (1.6%)	29 (2.5%)	18 (2.0%)	52 (2.2%)
DM diagnosed within 5 years prior to cancer diagnosis	0 (0.0%)	7 (2.3%)	38 (3.3%)	22 (2.4%)	67 (2.8%)
DM diagnosed 6 or more years prior to cancer diagnosis	2 (11.1%)	47 (15.2%)	389 (33.7%)	392 (43.1%)	830 (34.7%)
DM diagnosed after the cancer diagnosis	0 (0.0%)	9 (2.9%)	40 (3.5%)	17 (1.9%)	66 (2.8%)
DM not diagnosed	14 (77.8%)	203 (65.5%)	500 (43.3%)	368 (40.5%)	1,085 (45.4%)
TOTAL NUMBER OF PATIENTS DIAGNOSED WITH PANCREATIC CANCER (2021)	18 (100.0%)	310 (100.0%)	1,155 (100.0%)	909 (100.0%)	2,392 (100.0%)

Table 1. Mutual association of diabetes mellitus and pancreatic cancer within the period 2017-2021.

Results: There were 310,427 new cases of diabetes mellitus identified within the period 2017 - 2021. Over this period, an average of 2,448 people were diagnosed with pancreatic cancer per year (23.1 / 100,000 popula-

tion). In 2021, 2,064 patients > 60 years were diagnosed with pancreatic cancer. New onset of diabetes mellitus was recorded in 12.2% three years before the diagnosis of pancreatic cancer and four or five years before this diagnosis in another 5.2%. If we focus only on the 60-74 age group, the proportion was 13.8% and 5.8 %, respectively. Mutual association of diabetes mellitus and pancreatic cancer is displayed in Table 1.

Conclusion: Incidence of pancreatic cancer in the Czech Republic belongs to the highest ones in Europe. New-onset of diabetes mellitus precedes the diagnosis of pancreatic cancer in nearly 20 % of cases within a 5-year period. These findings lead to considerations of the introduction of an early detection programme for pancreatic cancer in the Czech Republic based on new-onset of diabetes mellitus and possible other risk factors.

Introduction: Due to the role of adipose tissue in mediating human metabolism, identification of prognostic biomarkers of fat loss in cancer cachexia are crucial to achieve better outcomes for cancer patients.

Aims & Methods: The aim of the study was to analyze the role of adipose-tissue derived adipokines in predicting cachexia in pancreatic cancer patients. We evaluated 71 patients with newly diagnosed pancreatic cancer. Serum adiponectin (ADP), leptin (L), ghrelin, tumor necrosis factor- α (TNF- α), and interleukin 6 (IL 6) were tested at baseline and after a follow-up period of 6 months. Our primary endpoint was 10% weight loss within 6 months. Receiver operating characteristics (ROC) analysis was employed to calculate the area under the curve (AUC). Survival analysis used the Kaplan-Meier curve and the Cox proportional hazards model.

Results: 53 of 71 patients met the primary endpoint. ADP levels were inversely correlated with leptin levels ($\rho = -0.433, P < 0.01$) in patients showing weight loss (WL). Thus, ADP concentration were corrected by leptin values (A/L ratio). Ghrelin, TNF- α and IL-6 levels showed an overall increase in the WL group, but the difference was statistically not significant. High A/L ratio was the only independent predictor of cachexia ($\beta = 0.655, P < 0.001$). At ROC analysis the diagnostic profile of A/L (AUC 0.932; sensitivity 82%; specificity 97%) in detecting cachexia was superior to that of leptin alone (AUC 0.698; sensitivity 70%; specificity 74%). Kaplan-Meier global survival analysis revealed a low A/L ratio was associated with an increased survival compared to patients with high A/L ratio (Cox F test = 2.260, $P < 0.05$).

Conclusion: Our results support the hypothesis that the combined measurement of adiponectin and leptin (A/L ratio) might provide prognostic information in predicting cachexia and survival in pancreatic cancer patients.

Introduction: Despite advances in treatment, overall survival for pancreatic cancer has not improved beyond a 5-year survival of 10%. Reasons for resistance to chemotherapy include a dense stroma, immunosuppressive environment, and poor vascularity within the primary pancreatic tumors. Vascularity within pancreatic tumors has been shown not to increase on contrast-enhanced harmonic EUS (CH-EUS) following 2 months of chemotherapy (Gemcitabine/Nab-Paclitaxel).

Preliminary data has suggested that endoscopic ultrasound (EUS) guided intra-tumoral injection of phosphorus-32 (³²P) microparticles in addition to standard chemotherapy is potentially beneficial in locally advanced pancreatic cancer (LAPC).

We aimed to assess vascularity changes within pancreatic tumors (via CH-EUS) following implantation of ³²P microparticles in combination with standard chemotherapy.

Aims & Methods: We performed a prospective single-center trial of patients with unresectable, non-metastatic locally advanced pancreatic cancer (LAPC) undergoing standard chemotherapy (FOLFIRINOX) and ³²P implantation after 2 or 3 cycles of chemotherapy. We perform EUS with contrast-enhanced harmonic EUS (CH-EUS) after 2 cycles of chemotherapy and at 4 weeks and 12 weeks after implantation of ³²P microparticles. Time intensity curve (TIC) analysis was performed over 90 seconds from IV contrast bolus with baseline intensity (prior to contrast bolus) and peak intensity obtained. Intensity gain was defined as median peak intensity – median baseline intensity.

Results: Twenty patients (45% male, median age: 65) have been enrolled in the trial with 15 patients completing 12-week follow-up (3 withdrawals, 1 death, 1 proceeded to surgery prior). Technical success of ³²P implantation was 100% with no procedural complications. Median longest primary tumor size reduced from 32mm (IQR 27.5-38.75) pre-implantation to 24mm (IQR 16-26) 12 weeks post-implantation ($p < 0.001$). Five patients (25%) thus far, have had tumor downstaging, with 3 resections (R1) and one pending.

One patient refused surgical treatment. All tumors demonstrated hypoenhancement (lower intensity of enhancement relative to surrounding normal pancreatic tissue suggestive of hypovascularity) at baseline. Median intensity gain of contrast enhancement within the tumor pre-implantation post median 2 cycles of chemotherapy, was 32.15 (IQR 18.08-54.35). Median intensity gain increased to 46.85 (IQR 35.05-76.6; $p = 0.007$) and 66.3 (IQR 54.7-76.3; $p = 0.001$) at 4 weeks and 12 weeks post implantation respectively. Over a median follow-up period of 7.4 months (IQR 5.1-14.6),

16/20 (80%) remain alive (estimated median survival time of 16.0 months) with 3/20 (15%) demonstrating both local and distant disease progression, whilst 3/20 (15%) have had distant progression only.

Conclusion: This is the first study to demonstrate increased vascularity within pancreatic primary tumors in response to ³²P implantation in addition to standard chemotherapy with FOLFIRINOX, whilst historical data has not supported vascularity changes in response to chemotherapy alone. The result of this current study forms a platform to understand further, the potential benefits of chemoradiotherapy over chemotherapy alone in patients with LAPC. Larger comparative trials are warranted.

Introduction: Defining pancreatic steatosis (PS) and establishing its association with pancreatic cancer has been a discussed theme in the last decade. However, no consensus guidelines have yet been published on the clinical relevance and management of PS. In this systematic review and meta-analysis, we investigated the association between PS and pancreatic ductal adenocarcinoma (PDAC).

Aims & Methods: Medical literature between 2007 and 2023 was reviewed for eligible trials investigating the prevalence of PS in patients with PDAC. Eligible studies reporting on PS, assessed via imaging or histology, were included. Our primary objective was to determine the association between PDAC and PS by comparing the prevalence of PS in individuals with- and without PDAC. Subsequently, an evaluation was conducted to determine whether the method of assessment (CT, MRI, EUS or histology) and study country was correlated with the association between PS and PDAC. Measures of effect size were determined using odds ratios (ORs) and corresponding 95% confidence intervals (95% CI).

Results: The systematic review identified a total of 23 studies, of which seventeen studies examined PS prevalence among PDAC patients. Overall, the pooled prevalence of PS in patients with PDAC was 53.6% (95% CI 40.9-66.2). No significant difference in PS prevalence was observed across various diagnostic methods or geographical regions ($p = 0.71$ and $p = 0.50$,

respectively). Overall, the pooled OR for PS in patients with PDAC compared to controls was 3.23 (95% CI 1.86-5.60, Figure 1). Subgroup analysis did not reveal any difference according to country ($p = 0.52$), but higher OR was observed in studies using EUS for the assessment of PS (pooled OR=6.26, 95% CI 1.23-31.8) compared to studies using CT (pooled OR=3.31, 95% CI 1.93-5.68), histology (pooled OR=1.76, 95% CI 1.22-2.54) or MRI (pooled OR=1.19, 95% CI 1.06-1.33).

Conclusion: Patients with PDAC have notable prevalence of pancreatic steatosis (53.6%). Furthermore, PDAC patients are significantly more likely to have PS (OR 3.23). These findings underscore the importance of prioritizing a standardized approach to the diagnosis, follow-up, and treatment of PS. Future studies should prioritize the identification of patients with PS who will benefit from PDAC surveillance programs.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) remains a challenge in oncology with an overall survival rate remaining about 10%. Surgery and adjuvant chemotherapy stands as only curative treatment options. Only a minority of patients are diagnosed with resectable disease. While traditional diagnostic modalities show limitations in detecting and monitoring pancreatic cancer, liquid biopsies is a relatively new, non-invasive and promising diagnostic method for early detection, molecular profiling, and observation.

Despite previous published or ongoing research projects and studies, liquid biopsies and specifically cell-free DNA (cfDNA) alterations role in management of pancreatic cancer remains unverified.

Aims & Methods: The aim of our study was to evaluate the diagnostic value of liquid biopsies and alterations in cfDNA levels in patients with pancreatic cancer. This study was approved by the Kaunas Regional Bioethics Committee (Approval ID: BE-2-31). Patients with newly diagnosed and histologically confirmed pancreatic cancer and patients with chronic pancreatitis, admitted to the Department of Surgery at Lithuanian University of Health Sciences Hospital, Kaunas Clinics, between September 2022 and December 2023, and healthy volunteers (control group) were included. Blood samples were obtained from the patients before any treatment procedures commenced. cfDNA was extracted from the collected blood using the QIAmp Circulating Nucleic Acid Kit (Qiagen).

The concentration and quality of the extracted cfDNA were determined using the Qubit™ 1X dsDNA High Sensitivity (HS) and Broad Range (BR) Assay Kits (ThermoFisher Scientific, Inc., Waltham, MA, USA). Mann-Whitney U-test and Kruskal-Wallis H-test were used to determine the differences in quantitative traits between the comparison groups, with results being presented in median (min – max). The predictive capability (diagnostic performance) of cfDNA to distinguish PDAC and chronic pancreatitis/healthy controls was investigated by means of the area under the ROC (Receiver-Operating Characteristics) curve (AUC).

Results: Sixty-five patients were included (47 patients with PDAC, 10 patients with chronic pancreatitis and 8 healthy controls). Levels of cfDNA were statistically significantly higher in PDAC patients (46.5 (4 - 768) ng/ml) compared to patients with chronic pancreatitis (23.4 (8.56 - 138.4) ng/ml) ($p = 0.032$) and healthy controls (19.75 (17.6 - 22.8) ng/ml) ($p < 0.001$). The cfDNA cut-off value distinguishing PDAC from chronic pancreatitis and healthy controls were determined to be 23,65 ng/ml (AUC = 0.716) and 22.9 ng/ml (AUC = 0.915), respectively. There were no differences in cfDNA levels concerning tumor localization, size, differentiation, spread, or survival rates (all $p > 0.05$).

Conclusion: Liquid biopsies and cfDNA level alterations offer promising opportunities for distinguishing pancreatic cancer from benign inflammatory diseases, such as chronic pancreatitis. However, additional experiments and studies are necessary for more comprehensive validation and clinical use.

Disclosure: This study was partially funded by Lithuanian University of Health Sciences Scientific fund and Lithuanian Future Biomedicine foundation.

Introduction: Matrix metalloproteinase-7 (MMP-7) and Syndecan-1 (SDC1) are involved in multiple functions during tumorigenesis. While most pancreatic ductal adenocarcinoma (PDAC) develop from Pancreatic Intraepithelial Neoplasia (PanIN), about 15-20% grows from well-defined pre-malignant cystic lesions. The presence of worrisome features in imaging cannot reliably differentiate cysts with neoplastic progression from those without. Therefore, implementation of new biomarkers is needed. MMP-7 has been shown to be overexpressed in both tissue and serum of patients with PDAC, but was never evaluated in pre-malignant cystic lesions. Similarly, SDC1, which has been linked to mutated overexpressed KRAS (the initiating step in most PDACs) and was recently shown by our lab to be elevated in PDAC, was not evaluated in cystic lesions yet.

Aims & Methods: To evaluate the diagnostic and prognostic performance of these serum proteins as potential panel biomarkers, in patients with PDAC and benign pancreatic cysts. In this, case-control study, patients with newly diagnosed PDAC (N= 121) were compared with benign cyst (N= 66) and healthy control (N=48) groups. Serum MMP-7 and SDC1 were measured by ELISA. The diagnostic accuracy of their levels for diagnosing PDAC and pancreatic cysts was computed, and their association with survival outcomes was evaluated.

Results: MMP-7 median serum levels were significantly elevated in PDAC (7.3 ng/ml) and cyst groups (3.7 ng/ml) compared with controls (2.9 ng/ml) ($p < 0.001$ and 0.02, respectively), and also between PDAC and cyst groups ($p < 0.001$), while SDC-1 median serum levels were significantly elevated in PDAC (43.3 ng/ml) compared with either cysts (30.1 ng/ml, $p <$

0.001) or controls (31.2 ng/ml, $P < 0.001$). The ROC analysis area under the curve (AUC) in PDAC vs. controls was 0.90 and 0.78 for MMP-7 and SDC-1, respectively, while it was 1.0 for the combination of the two and CA 19-9 ($p < 0.001$). Negative and positive predictive values of the 3 biomarkers panel were 100% and 79%, respectively. For patients with baseline serum MMP-7 ≤ 10 ng/ml vs. > 10 ng/ml, there was a trend for survival benefit after 1 year (50% vs. 36%, respectively; $p = 0.095$) and a significant benefit after 3 years (14% vs. 7%, respectively; $p = 0.016$). For patients with baseline serum SDC-1 < 35 ng/ml vs. ≥ 35 ng/ml, there was a trend for survival benefit after 1 year (52% vs 40%, respectively; $p = 0.06$) and no benefit after 3 years (19% vs. 20%, respectively; $p = 0.193$).

Conclusion: Despite a limited diagnostic utility as a biomarker for early detection of PDAC, this biomarker panel can safely rule out PDAC in healthy population

Introduction: Steatotic liver disease (SLD) is a common problem after liver transplantation (LT). Previous studies have confirmed the role of donor PNPLA3 rs738409 G allele as a risk factor for post-LT SLD, but the role of other recipient and donor genetic risk variants is largely unknown.

Aims & Methods: Aims: To study the prevalence of genetic risk variants for SLD in LT recipients and donors and their impact on development of post-LT SLD.

Methods: Of 807 adult patients undergoing LT in Finland between 2000–2019, 56 SLD-associated genetic risk variants were extracted from genotype data for 666 donor-recipient-pairs. Recipient genotypes were compared with ~10 000 Finnish population controls from gnomAD database. Incident post-LT SLD was assessed from protocol liver biopsies. The impact of donor and recipient genetic variants was studied in multivariate Cox regression analysis adjusted for phenotype factors.

Risk allele	Adjusted hazard ratio / number of risk alleles			p-values		
	0	1	2			p
Recipient PSD3 rs71519934-G	indicator	0.80	0.66	0.11	0.15	0.04
Recipient FADS1 rs174556-T	indicator	1.01	1.63	0.03	0.94	0.02
Recipient UCP2 rs695366-G	indicator	0.63	0.50	0.003	0.002	0.04
Donor MERTK rs4374383-A	indicator	1.51	1.46	0.02	0.007	0.10
Donor HSD17B13 rs6834314-G	indicator	0.68	0.46	0.02	0.02	0.07
Donor TM6SF2 rs58542926-T	indicator	1.61	1.71	0.08	0.03	0.46
Donor PNPLA3 rs738409-G	indicator	1.39	2.51	0.002	0.03	0.001

Table 1. Genetic variants significantly associated with post-LT SLD.

Results: Of 56 risk variants, the minor allele frequencies (MAFs) of 17 variants were significantly different between LT recipients and population controls. The greatest MAF differences were observed for PNP-LA3 rs738409-G (0.33 vs 0.22, $p = 2.56 \times 10^{-20}$), TNF rs1800629-A (0.19 vs 0.12, $p = 1.48 \times 10^{-12}$), IFNL4 rs12979860-T (0.29 vs 0.24, $p = 7 \times 10^{-6}$), CD14 rs2569190-A (0.41 vs 0.37, $p = 0.005$) and MERTK rs4374383-A (0.36 vs 0.33, $p = 0.014$).

Patients transplanted for metabolic dysfunction-associated steatohepatitis (MASH) ($n = 42$) exhibited high prevalence of PNPLA3 rs738409-G (0.63 vs 0.22, $p = 1.47 \times 10^{-19}$) and low prevalence of the protective HSD17B13 rs6834314-G (0.07 vs 0.21, $p = 0.001$) and MARC1 rs2642438-A (0.14 vs 0.29, $p = 0.002$).

Incidence of post-LT SLD was 29.1% in median follow-up time of 7.6 years. The lowest incidence (14.8%) was observed among patients transplanted for acute liver failure, and the highest (52.9%) in patients transplanted for MASH.

Final multivariate regression model to predict post-LT SLD included high SLD-risk indication (HR 2.03, $p < 0.001$), BMI (HR 1.10, $p < 0.001$), diabetes (HR 1.37, $p = 0.016$) and alcohol consumption (HR 2.01, $p < 0.001$). Table 1 shows the hazard ratios of the donor and recipient genetic variants most strongly predicting post-LT SLD after adjusting for recipient phenotype factors (high-SLD risk indication, BMI, diabetes, and alcohol consumption).

Conclusion: SLD-associated risk alleles were common in LT recipients, especially in MASH. Post-LT SLD incidence was high (29.1%), but with large variation across transplantation indications. Donor, but not recipient, PNPLA3 allele was most strongly associated with post-LT SLD. Several other donor and recipient genetic variants also contributed to post-LT SLD. Both LT recipient and donor genotypes provide novel insights into the genetic determinants of SLD after LT, providing help in future individual risk assessment.

Introduction: Some data suggest a possible association between metabolic dysfunction-associated steatotic liver disease (MASLD) and pancreatic disorders. However, evidence from population-based studies taking advantage of liver histology is lacking.

Aims & Methods: In this population-based cohort including all Swedish adults with biopsy-proven MASLD (1965-2017), we aimed to investigate the overall incidence of pancreatic diseases including acute and chronic pancreatitis, pancreatic cancer as well as pancreas-related mortality. Individuals with MASLD were matched to up to 5 individuals from the general population by age, sex, calendar year and county. Using the unique Swedish personal identity number, several validated nationwide registers were linked to obtain data on demographics, in- and outpatient diagnoses, prescribed medications, incident cancers, and causes of death. The primary endpoint of adverse pancreatic outcome was a composite of acute non-biliary pancreatitis, chronic pancreatitis, and pancreatic cancer. Secondary outcomes included each of the single outcomes as well as acute biliary pancreatitis and pancreas-related mortality. Using Cox proportional hazards modelling, we calculated multivariable adjusted HRs (aHRs). Sibling-controlled analyses were additionally performed to account for familial susceptibilities.

Results: In total, 8563 patients with biopsy-proven MASLD and 38,858 matched reference individuals were included. Among MASLD patients, the average age at index biopsy was 54.5 years, and 56.9% were male.

Overall, we documented 359 incident adverse pancreatic outcomes in MASLD patients (2.74/1,000 person-years (PYs)) and 880 events in matched reference individuals (1.19/1000 PYs), resulting in one extra case of adverse pancreatic outcome in 65 MASLD patients followed-up for ten years (incidence rate difference: 1.54/1000 PYs).

After multivariable adjustment, the aHR for incident adverse pancreatic outcomes was 2.19 (95%CI=1.92-2.50).

Compared with reference individuals, the incidence rate differences and corresponding aHRs increased with worsening histologic MASLD severity with 2.46 /1,000 PYs (aHR, 2.07 [95%CI=1.77-2.43]) in simple steatosis, 3.39 /1,000 PYs (aHR, 2.69 [95%CI=1.83-3.96]) in non-fibrotic MASH, and 3.56 /1,000 PYs (aHR, 2.53 [95%CI=1.87-3.43]) in patients with MASLD-associated fibrosis or cirrhosis, respectively.

Compared to reference individuals, the most common adverse pancreatic outcome in individuals with biopsy-proven MASLD was acute non-biliary pancreatitis with 1.44 vs. 0.44/1,000 PYs, resulting in an aHR of 2.24 (95%CI=1.83-2.75).

Consistent with the results on acute pancreatitis, individuals with MASLD had significantly higher rates of developing chronic pancreatitis (0.54 vs. 0.12/1,000 PYs; aHR 3.78, 95% CI 2.70-5.29).

In addition, MASLD patients had significantly higher rates of incident pancreatic cancer (0.88 vs. 0.47 per 1000 PY), resulting in an absolute rate difference of 0.41/1,000 PYs.

We documented 130 vs. 344 pancreas-related deaths among individuals with MASLD and their matched comparators (0.97 vs. 0.46/1,000 PY), yielding an absolute risk difference of 0.51/1,000 PY and an aHR of 2.41 (95%CI=1.95-2.97).

Conclusion: In this nationwide histology cohort, MASLD was associated with significantly higher rates of acute non-biliary pancreatitis, chronic pancreatitis, and pancreatic cancer, all of which led to a higher risk of pancreas-related mortality. In contrast, the risk of biliary pancreatitis was only slightly increased. Excess risk was evident across all stages of NAFLD and increased with worsening disease severity.

E2F1-HDAC1 COMPLEX TARGETS PIWIL1 TO REGULATE PANCREATIC STELLATE CELL ACTIVATION

R. Xue¹

¹Peking University Cancer Hospital and Institute, Department of Gastroenterology, Beijing, China

Contact E-Mail Address: xueran2@sina.com

Introduction: Pancreatic fibrosis is the main pathological feature of chronic pancreatitis. Activated pancreatic stellate cells (PSCs) are the main effector cells of pancreatic fibrosis.

The purpose of this study was to investigate the function of E2F1-HDAC1 complex in the activation of PSCs, evaluate the role of HDAC1 inhibitor Ce-

daramine during pancreatic fibrosis, and explore the molecular regulated mechanism between E2F1-HDAC1 complex and PIWIL1/mTOR signaling pathway.

Aims & Methods: When inducing pancreatic fibrosis in C57BL/6 mice, 20% L-arginine (250 mg/100g) was injected intraperitoneally twice a week, with an interval of 1 hour, lasting for 8 weeks, and then PSCs were isolated. Use RNA interference (RNAi) constructed by lentivirus and vectors constructed based on over-expression vectors to knock out and over-express E2F1 and HDAC1 Protein. In order to explore the effects of E2F1-HDAC1 complex on PSC activation and EMC secretion, western blotting and IHC staining were used respectively.

To explore transcriptional molecular mechanism between E2F1-HDAC1 complex and PIWIL1, luciferase reporter assay, chromatin immunoprecipitation (ChIP) and electrophoretic mobility shift assay (EMSA) were applied. Hematoxylin-eosin, Masson and Sirius red staining were used to analyze the effect of E2F1-HDAC1 complex and HDAC1 inhibitor Cedaramine on histological changes and collagen deposition.

Results: In LV-E2F1 and LV-HDAC1 group, the level of α -SMA, Col I and Col III were significantly increased compared with si-E2F1 and si-HDAC1 group. However, the expression of PIWIL1, desmin and p-mTOR were reduced in LV-E2F1 and LV-HDAC1 group. Meanwhile, E2F1-HDAC1 complex directly binded to the PIWIL1 promoter and then activated its transcription. In addition, as fibrosis aggravated over time, the levels of E2F1 and HDAC1 significantly increased. HDAC1 inhibitor Cedaramine can significantly improve collagen deposition in pancreatic fibrosis.

Conclusion: Our findings suggest that E2F1-HDAC1 complex targets PIWIL1 to regulate pancreatic stellate cell activation. HDAC1 inhibitor Cedaramine could become a potential drug in the treatment of pancreatic fibrosis.

MAS-DEPENDENT MACROPHAGE EFFEROCYTOSIS MAINTAINS IMMUNE HOMEOSTASIS IN ISCHEMIA-STRESSED MOUSE AND HUMAN LIVER

S. Chen¹, Z. Lu², S. Li¹, C. Yang¹

¹Tongji Hospital, School Of Medicine, Tongji University, Shanghai, China, ²Department of Automation, Tsinghua University, Beijing, China

Introduction: Liver ischemia-reperfusion injury (LIRI) is an inevitable detrimental event following liver transplantation, significantly impacting clinical outcomes. Novel therapeutic approaches are urgently needed to ameliorate recipient injury.

We recently has revealed the beneficial role of Mas receptor in drug-induced liver injury^[1, 2], which is also highlighted by the editorial of *Journal of Hepatology*^[3]. However, its specific roles in myeloid cell innate immunity and the maintenance of hepatic tissue homeostasis remain unclear.

Aims & Methods: The hepatic expression of Mas was investigated in ischemia-stressed mouse and human livers. Multiple cell-specific knockout mice were used to clarify the effector cells of Mas. Single-cell RNA sequencing (scRNA-seq), spatial transcriptomics (ST), multiplex Immunohistochemistry (mIHC), flow cytometry and subcellular intravital imaging were used to analyze macrophage efferocytosis and pathological interaction. RNA-seq, CUT&Tag and luciferase reporter assay were used for mo-

lecular studies. Adenovirus, mouse primary cells, Adeno-associated virus, *LysM^{cre}Klf4^{fl/fl}* mice and human liver samples were used to validate the discoveries of bioinformatics analysis.

Results: Long-term subcellular intravital imaging showed that macrophage efferocytosis occurs frequently during the early stage of LIRI and is crucial for the resolution of inflammation. Mice with systemic or myeloid cell-specific *Mas1* deficiency were vulnerable to LIRI. DAOSLIMIT, a novel intravital microscopy that fulfills the unmet requirement for hour-long, high-speed subcellular observations *in vivo*^[4]. scRNA-seq, ST, and intravital imaging collectively revealed that myeloid deficiency of *Mas1* results in impaired macrophage efferocytosis by downregulating MerTK, leading to the accumulation of aged neutrophils and exacerbating inflammation. Molecular studies demonstrate that Mas receptors regulate the transcription factor KLF4 via the PKA/CREB signaling pathway, thereby directly promoting the expression of macrophage MerTK. CUT&Tag, ChIP-qPCR and luciferase reporter assay revealed that the transcription factor KLF4 can directly bind to the promoter region of MerTK. Macrophage-specific knockout of KLF4 significantly exacerbated LIRI, and macrophage-specific overexpression of KLF4 *in vivo* effectively reversed the exacerbated phenotype caused by myeloid *Mas1* deficiency. mIHC also revealed that Mas⁺MerTK⁺ macrophages actively migrate towards aged neutrophils in ischemia-stressed human livers, thereby promptly clearing aged neutrophils.

Conclusion: In summary, our study documents a novel regulatory function of the Mas/KLF4/MerTK axis via PKA/CREB signaling in macrophage efferocytosis. It may serve as a therapeutic target and as a checkpoint regulator of homeostasis in response to LIRI. By combining scRNA-seq, ST and intravital imaging, this work provides a comprehensive paradigm for studying mammalian cellular interactions in complex pathophysiological microenvironments.

NEW INSIGHT OF LIVER FIBROSIS: ALTERED CHROMATIN ACCESSIBILITY IN HEPATIC STELLATE CELLS

T. Jia¹, Y. Shen¹, L. Yang¹

¹West China Hospital of Sichuan University, Department of Gastroenterology and Hepatology and Sichuan University-University of Oxford Huaxi Joint Centre for Gastrointestinal Cancer, Chengdu, China

Contact E-Mail Address: 2018151621145@stu.scu.edu.cn

Introduction: The treatments for liver fibrosis are still in need so far. As the crucial initiators, activated hepatic stellate cells (aHSCs) undergo a series of epigenetic changes.

The study intends to explore transcription factors (TFs) that facilitate HSCs activation and provide novel therapeutic targets for liver fibrosis.

Aims & Methods: Three distinct HSCs activation models were established in present study.

Firstly, *in vitro* activation involved isolating primary HSCs from normal Sprague-Dawley rats and culturing them for two days (n=5) and seven days (n=5), namely natural activation model.

Secondly, *in vivo* activation entailed isolating primary HSCs from bile duct ligated rats (n=4) and normal controls (n=4), followed by culturing until the next day. Lastly, transforming growth factor- β (TGF- β , 2.5ng/ml) (n=10) or control buffer (n=10) were added to the human HSCs cell line LX2 and cultured for 24 hours. Subsequently, assay for transposase-accessible chromatin using sequencing (ATAC-seq) was conducted on the abovementioned cells, along with motif enrichment and footprint analysis.

Pathway enrichment analysis was performed on differentially accessible genes (DAGs). RNA sequencing (RNA-seq) was employed to analyze gene expression profiles of primary HSCs in the natural activation model (n=4).

The integration of ATAC-seq and RNA-seq further identified potential key TFs. RT-qPCR and differential expression analysis of public datasets was utilized to confirm the dysregulation of TFs in primary HSCs, fibrotic liver and fibrotic model of induced pluripotent stem cells.

Finally, enrichment at enhancers and promoters of these genes was validated by H3K27Ac and H3K4me3 chromatin immunoprecipitation followed by sequencing (ChIP-seq) of human HSCs.

Results: For ATAC-seq, primary HSCs exhibited higher chromatin accessibility after activation compared with the controls. After peak annotation, the up-regulated peaks were mainly located in the promoter region in all comparison groups, uncovering the dynamic transcriptional regulation during HSC activation. In the motif enrichment analysis, 150 aHSCs related TFs and 54 quiescent HSCs (qHSCs) related TFs were identified in the *in vitro* activation model.

The three models shared 12 aHSCs related TFs, namely *Runx-aml*, *Runx1*, *Runx2*, *Runx*, *Ets:Runx*, *Atf2*, *Atf4*, *Atf7*, *c-Jun-Cre*, *Creb5*, *Smad3* and *CArG*; and 19 qHSCs related TFs, including *Foxf1*, *Foxo3*, *Foxk1*, *Foxp1*, *Hoxa1*, *Hoxa2*, *Stat3*, *Hnf4a*, *Hnf6*, *Elk1*, *Elk4*, *Cux1*, *Crx*, *Duxbl*, *Vdr*, *Tr4*, *Ebf2*, *Gata2*, *Gata6*. Footprint analysis validated the alteration of accessibility in *Atf2*, *Atf4*, *Atf7*, *Creb5*, *Hnf6* and *Gata2*.

Actin filament organization, Ras protein signal transduction and intrinsic apoptotic signal pathways were enriched in DAGs. Integration of ATAC-seq and RNA-seq showed that gene expression was significantly correlated with chromatin accessibility, among which *Runx2*, *Creb5*, and *Smad3* were significantly upregulated in aHSCs at transcription level. The dysregulation of these three genes was verified in primary HSCs, fibrotic liver and fibrotic model of human induced pluripotent stem cells.

Finally, enrichment at active enhancers and promoters of these TFs was validated by H3K27Ac and H3K4me3 ChIP-seq of human HSCs, revealing the crucial role of genes in the transcription.

Conclusion: We generated chromatin accessibility profiles of different HSCs activation models, highlighting the significance of *Runx2*, *Creb5*, and *Smad3* as key TFs mediating HSCs activation. These findings proposed these TFs as promising targets for future liver fibrosis treatment.

JUND-REGULATED GLUTAMINE METABOLISM IN PANCREATIC STELLATE CELLS PROMOTES PANCREATIC FIBROSIS VIA PIWIL1/MTOR SIGNALING PATHWAY

R. Xue¹

¹Peking University Cancer Hospital and Institute, Department of Gastroenterology, Beijing, China

Contact E-Mail Address: xueran2@sina.com

Introduction: Pancreatic fibrosis is the main pathological feature of chronic pancreatitis and stroma of pancreatic cancer, which is the result of excessive deposition of extracellular matrix of collagen fibers. Activated pancreatic stellate cells (PSCs) are the main effector cells of pancreatic fibrosis. The characteristics of heterogeneity and subgroup of PSCs may help to determine the therapeutic target of pancreatic fibrosis. The purpose of this study was to investigate the function of JUND in the activation of PSCs, evaluate the role of JUND in glutamine metabolism during pancreatic fibrosis, and explore the molecular regulated mechanism between JUND and PIWIL1/mTOR signaling pathway.

Aims & Methods: When inducing pancreatic fibrosis in C57BL/6 mice, 20% L-arginine (250 mg/100g) was injected intraperitoneally twice a week, with an interval of 1 hour, lasting for 8 weeks, and then PSCs were isolated. Use RNA interference (RNAi) constructed by lentivirus and vectors constructed based on over-expression vectors to knock out and over-express JUND and PIWIL1 Protein. In order to explore the effects of JUND on PSC activation, EMC secretion, actin cytoskeleton, invasion and migration ability, as well as glutamine metabolism, ELISA, western blotting, wound healing test, transwell and phalloidin staining were used respectively. To explore transcriptional molecular mechanism between JUND and PIWIL1, luciferase reporter assay, chromatin immunoprecipitation (ChIP) and electrophoretic mobility shift assay (EMSA) were applied. Hematoxylin-eosin, Masson and Sirius red staining were used to analyze the effect of JUND on histological changes and collagen deposition.

Results: In LV-JUND group, the level of α -SMA, Col I and Col III were significantly increased compared with si-JUND group. However, the expression of PIWIL1, desmin and p-mTOR were reduced in LV-JUND group. Meanwhile, the synthesis and metabolism of glutamine decreased significantly under the LV-JUND treatment. Wound healing test, transwell indicated that JUND promoted the migration and invasion ability of PSCs. Furthermore, JUND directly binded to the PIWIL1 promoter and then activated its transcription. In addition, as fibrosis aggravated over time, the levels of JUND significantly increased.

Conclusion: Our findings suggest that JUND-regulated glutamine metabolism in PSCs promotes pancreatic fibrosis via PIWIL1/mTOR signaling pathway. JUND could become a potential target for the treatment of pancreatic fibrosis.

Introduction: *KRAS*, *TP53*, *CDKN2A*, and *SMAD4* have been the main driver mutations in pancreatic ductal adenocarcinoma (PDAC). Studies on the clinical significance and treatment response to 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX) regimen in terms of the presence of these mutations remain inconclusive.

Aims & Methods: This study analyzed patients diagnosed with pancreatic adenocarcinoma using a targeted next-generation sequencing platform at two tertiary referral hospitals from January 2016 to March 2022. Patients receiving FOLFIRINOX chemotherapy as the initial treatment were retrospectively investigated.

Results: The analysis included 100 patients. *KRAS* mutation was identified in 92 (92.0%) patients, followed by *TP53*, *CDKN2A*, and *SMAD4* in 63 (63.0%), 18 (18.0%), and 17 (17.0%) patients, respectively. The *TP53* wild type group demonstrated longer overall survival (OS) than the *TP53* mutated group (median OS: 29 months vs. 19 months, $p = 0.03$), and *TP53* served as a prognostic factor for survival (hazard ratio = 1.74, 95% confidence interval: 1.00–3.00, $p = 0.048$). The difference in OS according to *TP53* mutation was intensified in localized pancreatic adenocarcinoma (37 months vs. 19 months, $p = 0.01$). The *TP53* wild type group demonstrated a higher objective response rate to FOLFIRINOX chemotherapy than the *TP53* mutation group in localized pancreatic adenocarcinoma (50.0% vs. 17.6%, $p = 0.024$).

Conclusion: PDAC patients with wild type *TP53* demonstrated longer OS than those with *TP53* mutation, and this trend was intensified in patients with localized disease. This result may be due to an impaired response to FOLFIRINOX chemotherapy in patients with *TP53* mutation.

Disclosure: Nothing to disclose.

GENOME-WIDE META-ANALYSIS ASSOCIATES DONOR-RECIPIENT NON-HLA GENETIC MISMATCH WITH ACUTE CELLULAR REJECTION AFTER LIVER TRANSPLANTATION

Introduction: Acute cellular rejection (ACR) remains a common complication causing significant morbidity after liver transplantation.^{1,2}

Recent studies suggest that the proportion of non-HLA mismatched SNPs, referring to all SNPs outside the HLA region, also known as major histocompatibility complex (MHC), was associated with increased rejection risk after kidney transplantation.³⁻⁶

This is currently unexplored in liver transplantation.

Aims & Methods: We aimed to investigate whether donor-recipient non-HLA genetic mismatch is associated with increased incidence of biopsy-proven grade 2/3 ACR, hereafter referred to solely as ACR, within 1-year after liver transplantation. We conducted an international multicenter case-control genome-wide association study of donor and liver transplant recipient pairs in three independent cohorts, totaling 1846 pairs. To assess the burden of donor-recipient genetic incompatibility, we calculated sum scores for single nucleotide polymorphism (SNP) mismatch based on all non-HLA functional SNPs.

Additionally, we performed an analysis specifically including only SNPs coding for transmembrane or secreted proteins, which are more likely to affect the immune system.

We analyzed the association between the log-normalized non-HLA mismatch scores and ACR in a multivariable cox regression model per cohort, followed by a weighted meta-analysis.

Results: During the first-year post-transplantation, 90 of 689 (13%), 161 of 720 (22%) and 48 of 437 (11%) recipients experienced ACR in cohorts 1-3, respectively. After correcting for potential confounders using multivariable cox regression analysis, our weighted meta-analyses showed that higher mismatch in functional non-HLA SNPs was associated with increased incidence of 1-year ACR (HR 5.31; 95%CI 1.39-20.08; $P=0.015$). Moreover, we also confirmed the effect of mismatch in the subset of SNPs coding only for transmembrane or secreted proteins on 1-year ACR (HR 6.69; 95%CI 1.82-24.78; $P=0.004$).

Conclusion: In this multi-center genome-wide meta-analysis we show that genetic non-HLA incompatibility between donors and recipients is an important independent predictor of ACR after liver transplantation. Donor-recipient mismatch of functional non-HLA SNPs overall and, especially, of SNPs coding for transmembrane or secreted proteins correlated with ACR developed within the first year after liver transplantation. Identifying high-risk immunological burden between donor-recipient pairs may potentially prevent early graft rejection and help future efforts to personalize immuno-suppressive medication. This is important as immune suppressive medication causes significant morbidity and mortality.

IDENTIFYING DRIVERS OF PATIENT PREFERENCE IN THE TREATMENT OF PRURITUS IN PRIMARY BILIARY CHOLANGITIS

A. Halliday¹, H.T. Smith¹, D. Szinay², A. Walker¹, P.J.F. Troke¹, K. Meginnis³, S. Heidenreich², J. Seo⁴

¹GSK, London, United Kingdom, ²Evidera, London, United Kingdom, ³Evidera, Glasgow, United Kingdom, ⁴Evidera, Bethesda, United States of America

Contact E-Mail Address: phil.j.troke@gsk.com

Introduction: Pruritus is common in primary biliary cholangitis (PBC) and can significantly impact patients' quality of life (QoL). Cholestyramine is recommended as the first-line treatment option for pruritus in PBC, but tolerability, inconvenient administration, and limited efficacy data restrict its use. Patient-focused drug development can help address this unmet need, but an understanding of patients' perspectives on pruritus and treatments is required. This study conducted semi-structured qualitative patient interviews to explore patients' experiences, expectations, and concerns with regards to pruritus and treatments.

Aims & Methods: Semi-structured virtual interviews were designed following a literature review and conducted with patients from the USA, Germany, UK, and Italy. Eligible patients self-reported a PBC diagnosis and had a worst itch score of ≥ 4 on a 0-10 numerical rating scale (NRS) in the past 2 months. Interviews had four parts:

- 1) pruritus experience,
- 2) treatment desires and concerns,
- 3) treatment experience,
- 4) hypothetical choice questions that required patients to make trade-offs between two options.

Responses were used in an inductive thematic analysis and visually summarized.

Results: Ten patients per country were interviewed (N=40); most were female (78%) and mean (standard deviation) age was 52.5 (15.2) years. For 53% (n=21), pruritus had started within the last 3 years. On the NRS, patients rated their pruritus over the last 2 months on average as mean 5.4 (range 2-10), and worst itch as mean 7.1 (range 4-10). Key themes that emerged from patient discussions were visualized with a concept map.

Pruritus was widespread over patients' bodies, persistent despite scratching, and described as 'crawling', 'burning' and 'nettles'. Pruritus impacted social interactions, sleep quality, appearance, emotional stability, and work productivity. Many patients wished for complete resolution, but primarily wanted treatment to reduce pruritus severity (60%; n=23). Of those who had ever received cholestyramine (n=12), 62% reported a repulsive taste and texture; 50% mentioned concerns about interactions between cholestyramine and PBC medication. From five potential pruritus medication side effects, diarrhea and nausea were of greatest concern.

Conclusion: Pruritus impacts QoL in PBC in several ways and the limitations of existing treatments mean patients would welcome alternative options. Future research will establish the relative importance to patients of treatment aspects such as administration, benefits, and tolerability.

Introduction: The worldwide prevalence of diabetes is increasing and while there are numerous studies on the impact of prediabetes and diabetes on cancer incidence, research focusing on the Korean population is scarce.

Aims & Methods: This study aimed to evaluate whether prediabetes, diabetes, and poorly controlled diabetes in the Korean population affect the risk of the incidence of various types of gastrointestinal cancers using integrated data of two public datasets. Combining data from the National Health Insurance Service (NHIS) and Korean National Health and Nutrition Examination Survey (KNHANES) from 2013 to 2021, we generated integrated datasets using 3 key identifiers: name, gender, and date of birth. Subsequently, a retrospective cohort study was performed using the combined cohort to enroll subjects aged 20 years or older from 2014 to 2019 (N = 30,684) and followed up until 2021. The 4 groups were defined as follows: group 1 (non-diabetic individuals): hemoglobin A1c (HbA1c) < 5.7% and fasting glucose level (FBS) < 100 mg/dL, group 2 (prediabetes): no diabetes and 5.7% ≤ HbA1c < 6.5% or 100 ≤ FBS < 125 mg/dL, group 3 (controlled diabetes): diagnosed as diabetes and HbA1c < 8.0%, and group 4 (uncontrolled diabetes): diagnosed as diabetes and HbA1c ≥ 8.0%. Covariates including age, sex, alcohol consumption, smoking status, body mass index, total cholesterol, hypertension, income level were adjusted for, and cancer diagnoses were determined using both claim ICD-10 C codes and cancer-specified diagnosis code (V193). We evaluated the risk of overall cancer and gastrointestinal cancers including stomach, colorectal, pancreatic, bile duct, and liver cancers in the 4 groups.

Results: In the final dataset, 24,058 individuals were included, and 675 subjects (2.8 %) developed any cancers during the follow-up. Compared to group 1 (reference), overall cancer risk was significantly increased in the groups 2-4 (adjusted hazard ratio [95% confidence interval]; 1.249 [1.05-1.487], 1.990 [1.511-2.613], and 2.435 [1.305-4.544] in the groups 2, 3, and 4, respectively; $p_{\text{trend}} < 0.001$.) Among gastrointestinal cancers, the risk of pancreatic cancer was significantly increased in group 2 as well as group 3 (1.249 [1.050-1.487] and 6.412 [1.870 – 21.983], respectively.); the risk of liver cancer was increased in the groups 3 and 4 (2.407 [1.095 – 5.291] and 5.483 [1.413-21.28], respectively). For stomach and bile duct cancers, the risk was significantly increased only in group 4 (6.349 [2.296-17.557] and 8.676 [1.339-56.228], respectively.) Colorectal cancer risk also showed a positive correlation with diabetes, which did not reach a statistical significance ($p > 0.05$).

Conclusion: We conducted a novel retrospective cohort study using the integrated dataset of NHIS and KNHANES. Diabetes and prediabetes are risk factors for various types of cancer. The impact of diabetes on gastrointestinal cancers varies possibly depending on the mechanism specific to each cancer type, including the presence or absence of glycemic control, the presence of diabetes, and the prediabetes status.

EVALUATING THE ALLURION ELIPSE® GASTRIC BALLOON: A NON-INVASIVE AND RESOURCE-EFFICIENT WEIGHT LOSS SOLUTION DURING THE COVID-19 PANDEMIC

C. Simeth¹, M. Campigotto¹, M. Giuffrè^{2,3}, I.V. Albergati³, F. Monica¹
¹Azienda Sanitaria Universitaria Giuliano Isontina, Gastroenterologia ed Endoscopia Digestiva, Trieste, Italy, ²Yale School of Medicine, Department of Internal Medicine (Digestive Diseases), New Haven, United States of America, ³Università degli Studi di Trieste, Dipartimento universitario clinico di scienze mediche, chirurgiche e della salute, Trieste, Italy

Introduction: Since the global emergence of the COVID-19 pandemic in Spring 2020, numerous bariatric units worldwide have indefinitely postponed elective weight loss procedures, responding to the heightened risk profile associated with obesity during viral infections. Concomitantly, lockdown measures have led to significant lifestyle changes, notably reductions in physical activity and increases in food consumption, collectively contributing to weight gain in various populations. Intra-gastric balloons, recognized as effective means for initiating weight loss or serving as an interim solution before bariatric surgery, require upper endoscopy for insertion and removal. These procedures have faced significant disruptions due to the pandemic-driven reallocation of medical resources, including anesthesiologists and endoscopic services.

Aims & Methods: This study aims to evaluate the feasibility and safety of employing the Allurion Elipse® gastric balloon, an innovative device designed for administration without anesthesia or endoscopic guidance. This device could potentially reduce patient risk and conserve valuable hospital resources in times of medical crisis. A selected group of obese patients, as determined by our multidisciplinary bariatric team, were administered an encapsulated pill balloon, which, once ingested, expands with 550mL of fluid under the direct supervision of a gastroenterologist. Placement accuracy was confirmed through X-ray imaging. Alongside the physical intervention, patients received comprehensive support, including a customized diet plan, access to a digital health application connected to a weighing scale for remote monitoring, and regular virtual follow-ups. The primary measure of clinical efficacy was the percentage of total body weight loss (%TBWL).

Results: The study included seventeen consecutive patients (11 females, 6 males) with a mean age of 43.7 ± 9.9 years. These individuals had a mean weight of 104.21 ± 21.72 kilograms and a mean BMI of 36.11 ± 4.7 kg/m2. The balloon positioning procedures were efficiently completed in 20 to 30 minutes without technical complications. Most patients reported transient nausea and vomiting. However, these symptoms were manageable and did not lead to any severe adverse events. Only one patient required early balloon removal due to intolerance.

After eight months of the procedure, with the balloon passing naturally four months prior, two patients reported a %TBWL of 19.8. The average %TBWL recorded at the four-month mark was 13%, and the weekly check-in compliance rate was 62%.

Conclusion: The COVID-19 pandemic has drastically impacted the availability and functionality of bariatric and endoscopic services, prompting the need for alternative methods that simplify and expedite the weight loss process. Although limited, the available data support the Allurion Program with the Elipse Balloon as a non-invasive, secure, and effective method to manage obesity. It facilitates rapid and sustainable weight loss, enables continuous remote support, and minimizes the impact on patients and the already strained health systems. This method represents a valuable alternative to traditional approaches, particularly during health-care resource constraints.

Introduction: Endoscopic Sleeve Gastroplasty (ESG) is one of the main interventions of primary minimally invasive bariatric surgery, especially for subjects suffering from I and II class obesity^{1,2}. However, since obesity is a chronic, relapsing, and multifactorial disease, a second intervention may be necessary. The purpose of this study is to assess the effectiveness of endoscopic revision (Re-ESG) versus primary intervention (P-ESG).

Aims & Methods: A prospective dataset enrolling all subjects undergone ESG in a tertiary center from May 2017 to December 2023 was retrospectively analyzed. All subjects undergone Re-ESG for weight regain (WR), weight plateau (WP) or weight loss failure (WF), as defined by Lopez Nava et al.³, were enrolled. Weight loss outcomes [Absolute Weight Loss (AWL), Excess Weight Loss (EWL), Total Body Weight Loss (TBWL), Body Mass Index Loss (BMIL)] at 6-,12-,18- and 24-months after P-ESG and Re-ESG were collected and compared.

Results: Out of a total of 578 patients, 53 patients (9.2%) underwent Re-ESG: 24 for WR, 18 for WP and 12 for WF, after a mean time of 25.4 ± 11.4 months from P-ESG (35 subjects underwent revision in the first 24 months, whereas other 18 between 30 and 66 months). One subject underwent a second revision, for a total of 54 revisions.

Both P-ESG and Re-ESG were associated with significant total body weight loss and excess body weight loss up to 24 months and when compared, endoscopic revision were proven to be as effective as primary intervention, at least in the short and medium term, as showed in Table 1.

	6-months				12-months				18-months				24-months			
	AWL (kg)	EWL (%)	TBWL (%)	p	AWL (kg)	EWL (%)	TBWL (%)	p	AWL (kg)	EWL (%)	TBWL (%)	p	AWL (kg)	EWL (%)	TBWL (%)	p
P-ESG	18.4 (7.9)	55.2 (24.5)	17.3 (6.7)	<0.01	17.9 (9.7)	52.9 (27.7)	16.7 (8.2)	<0.01	18.1 (10.5)	50.0 (22.7)	16.6 (8.3)	<0.01	16.3 (11.9)	45.7 (32.7)	15.1 (10.6)	<0.01
Re-ESG	15.0 (7.7)	52.9 (23.5)	14.7 (6.1)	<0.01	17.0 (8.0)	55.7 (21.8)	16.5 (7.2)	<0.01	11.9 (10.9)	41.4 (44.2)	11.4 (11.0)	<0.01	7.3 (11.8)	25.4 (25.9)	7.0 (9.2)	0.937
P	0.32	0.571	0.434		0.712	0.684	0.924		0.121	0.569	0.128		0.122	0.183	0.109	

Table 1. Comparison of weight loss outcomes between primary ESG and endoscopic revision (Re-ESG) at 6-,12-,18- and 24-months follow-up. Data are reported as mean value (standard deviation). A two sample T-Test was used to compare baseline weight and weight loss outcomes. ESG=Endoscopic Sleeve Gastroplasty; P-ESG= Primary ESG; Re-ESG= Revision of ESG; AWL=Absolute weight loss; EWL=Excess weight loss; TBWL=Total body weight loss.

Conclusion: Our study, despite the limit of a low sample, highlights how the endoscopic revision of a previous ESG is as effective as the primary intervention in the short and medium term.

These results may pave the way for an exclusively minimal-invasive multi-step treatment of chronic obesity.

Introduction: Obesity awareness has recently increased following its pandemic evolution. Besides nutritional and lifestyle modifications and pharmacological therapy, many other therapeutic strategies have been evaluated, with fluid-filled intragastric balloon (FF-IB) being the most prevalent. There is still no consensus around which is the best filling volume for FF-IB, that is usually filled according to the physician's expertise, with the purpose to tailor the filling on patient's BMI and stomach shape.

This study aimed to find out any differences in terms of outcomes of different FF-IB's filling volume.

Aims & Methods: This was a single-center, observational prospective study of obese patients undergoing FF-IB (Medsil, Orbera) for 6 months, with a random filling volume of 500, 600, or 700 ml of saline and Methylene Blue (fig.1). The outcomes were evaluation of early post-procedural complications (pain, nausea and/or vomiting in the first 24 hours), percentage of early removal for intolerance, percentage of Total Body Weight Loss (TBWL%) and percentage of Excess Weight Loss (EWL%) at 6 months follow-up, quality of Life (QoL, measured by EQ-5D test) at 1, 3, and 6 months follow-up and modifications of blood tests and blood pressure at 6 months.

Results: Between July 2020 and May 2023, 180 obese patients (41.7±9.02 kg/m², 46.2±14 years, 70% female, 53% obesity class III, Fatty Liver Disease as the main comorbidity; other baseline characteristics in table 1) underwent a FF-IB placement, that was removed after 180±12 days. Pain was the most frequent complication in the first 24 hours, being encountered in 77.5 % of patients, while nausea and/or vomiting were detected in 50.7 % of cases; no differences were observed among the three groups with different filling volume (pain p=0.180, nausea p=0.718, and vomiting p=0.480). Early removal was detected at a mean time of 75±43 days in 19 patients (10.6 %), with no differences among the 3 groups (p=0.870). At 6 months follow-up the mean TBWL% was 14.6±7.14, EWL% was 30.8±23.30, with no differences among the three groups (p=0.882 and p=0.733, respectively). QoL at 1, 3, and 6 months follow-up significantly improved from the baseline in each time frame (p<0.001) and this improvement was the same among the three groups (p=0.819, p=0.822, p=0.849). Mean levels of cholesterol, triglycerides, low-density lipoprotein, and HbA1c, as well as systolic and diastolic blood pressure, were significantly improved at 6 months after FF-IB placement (P<0.05), and no differences among the three groups of filling volume were detected.

Conclusion: An IB's filling volume of 500, 600, or 700 ml seems to give the same outcomes in terms of post-procedural complications, percentage of early removal, TBWL%, EWL%, QoL, and improvement of blood tests and blood pressure, regardless of the baseline characteristics of patients.

Introduction: Obesity is associated with gut dysbiosis, partially restored after a nutritional or surgical intervention. In the latter, the anatomical modification due to bariatric surgery, together with multiple antibiotic therapies, could be responsible for heterogeneous reported results. Endoscopic Sleeve Gastroplasty (ESG) is a new effective and minimally invasive treatment for patients with obesity (PWO).

Aims & Methods: This prospective observational study aimed to assess the effects of the ESG treatment on weight loss and gut microbiota. Adult PWOs were consecutively enrolled and underwent ESG at the Endoscopy Unit of Fondazione Policlinico Campus Bio-medico of Rome. At the baseline (T0) and at four (T1) and eight (T2) months (T1) after ESG,

anthropometric parameters (body weight, BMI, waist (WC), hip (HC), neck (NC) circumferences), blood pressure and heart rate measurement, and the food frequencies questionnaire (FFQ) were collected. Moreover, stool samples were collected at each visit, then analyzed using Next Generation Sequencing techniques (NGS). Significance was assessed for a p -value < 0.05.

Results: A total of 29 patients were enrolled in this study; at present, 15 patients completed the T1 and 10 the T2. No procedural complications were observed; none of the patients required antibiotic therapy after the endoscopic procedure. Body weight and BMI significantly decreased at T1 ($p=0.0358$ and $p=0.0263$, respectively) and T2 ($p=0.0297$ and $p=0.0080$, respectively) compared to the baseline. HC significantly decreased between T0 and T2 ($p=0.0057$) while WC and NC showed a decreasing trend. Maximum blood pressure decreased from T0 to T1 ($p=0.0125$). Regarding FFQ no statistical changes were observed in their food habits at each visit.

After 4 months participants reduced the consumption of semi – skimmed milk, aged cheeses, red meat, eggs, vegetables, fruit, pasta, rice, bread and burger in the bun and increased the consumption of fresh cheeses, white meat, fish, coffee, alcoholic beverages, soft drinks and sugar. The consumption of semi – skimmed milk, fresh cheeses, red meat, eggs, pasta, rice, bread, vegetables and fruits and coffee increased again at t2. The consumption of fruit was almost of 1 fruit per day while the consumption of red meat after 8 months was 2 times/week, more than what is reported in nutritional recommendations.

Regarding microbiota composition, the mean value of richness, biodiversity index and dysbiosis index at T0 were 167.13 ± 41.22 , 8.71 ± 1.97 and 1.15 ± 1.83 , respectively. After 4 and 8 months an increasing trend in richness (174.71 ± 38.56 and 207 ± 22.87 , respectively) and biodiversity (8.93 ± 2.25 and 10.75 ± 2.1 , respectively) was observed even if not statistically significant. Dysbiosis decreased significantly at T2 (0.027 ± 0.03) compared to baseline ($p=0.0419$).

No significant differences were found at phyla and family levels at each time compared to baseline: an interesting increasing trend of Akkermansia Muciniphila was observed at T1 (2.08 ± 6.62) compared to T0 (0.53 ± 1.1) values. This result was maintained until T2 without significant changes.

Conclusion: Preliminary results of the present study confirm the effectiveness of ESG in reducing body weight without significant post-operative complications. It seems to positively modulate the intestinal microbiota, partially increasing some beneficial species such as A. Muciniphila.

Disclosure: Nothing to disclose.

BREATH-BASED MONITORING OF MICROBIOME METABOLIC RESPONSES BEFORE AND AFTER INGESTION OF NUTRIENTS

A. Tawfike¹, A. Murgia¹, I. Banda¹, Y. Ahmed¹, M. Manhota¹, D. Fonseca¹, F. Ricciardi¹, K. Sweeney¹, L. Nicholson-Scott¹, L. McConville¹, E. Crone¹, E. Piscitelli¹, O. Gandelman¹, M. Allsworth¹, B. Boyle¹, G. Ferrandino¹

¹Owlstone Medical Limited, Cambridge, United Kingdom

Contact E-Mail Address: Elizabeth.Crone@owlstone.co.uk

Introduction: The nutrients we ingest also feed the microbiome that lives in our digestive system. The resulting metabolic products may have beneficial or deleterious effects on our health. For example, ethanol and 2-3-butanediol, produced by carbohydrate fermentation, were found to be associated with non-alcoholic steatohepatitis (NASH).

Interestingly, several microbiome-derived metabolites are volatile organic compounds (VOCs) that can be measured in breath. In this ongoing study, we explored the feasibility of microbiome metabolic characterization before and after carbohydrate or amino acid ingestion.

Aims & Methods: A total of 13 healthy subjects were recruited with age ≥ 18 years and body weight ≥ 50 Kg. Subjects were instructed to fast overnight and to not drink alcoholic beverages the day before the experiments. Breath samples were collected before, and up to 90 minutes after ingestion of 75 g of glucose, cysteine, or tryptophan, with a time resolution of 5 minutes. Compounds of interest were measured using Soft Ionization Flow Tube Mass Spectrometry (SIFT-MS) with direct sampling. Results were expressed as part per billion (PPB v) as a function of time post-glucose ingestion.

Results: Intraoral swishing of 250 mg/mL glucose in water for 30 seconds, followed by spitting, elicits a peak of ethanol within 10-15 minutes that disappears after 25-30 minutes. However, ingestion of 300 mL of the same solution showed a variable response among different subjects. Some individuals showed a peak after 15 minutes, others, after 30-50 minutes (Fig. 1). Median (M) and interquartile range (IQR) baselines levels (before glucose administration) of ethanol, were 99.4 [71.6-182.4] PPB. Post glucose ingestion, breath peak levels ranged between 130, and 1600 PPB. Similarly, glucose administration induced spikes of acetoin, and propanoic acid, with ranges of 7-20 PPB and 18-160 PPB, respectively. Administration of tryptophan and cysteine elicits spikes of p-cresol, phenol, and hydrogen sulfide. Additional compounds were also detected, such as trimethylamine (M: 42.3, IQR: 33.6-54.3 PPB), methanol (M: 443, IQR: 199-531.4 PPB), and methane (M: 26988, IQR: 10100-76213 PPB).

Conclusion: Breath analysis is suitable for the clinical characterization of microbiome metabolism in the digestive system in healthy and disease populations to establish correlations between metabolites and disease severity and progression, as well as investigate the interaction of gut microbiota in response to therapeutic interventions. We aim to expand this approach to carbohydrates of different complexity, other amino acids, and nutrients (Table 1). This non-invasive method can replace the current need for blood collection enabling easier scaling to large cohort populations.

STOOL MICROBIOME CHARACTERISTICS DIFFER BETWEEN ADULTS WITH IBS AND HEALTHY CONTROLS AND CORRELATE TO USUAL AND 24-HOUR RECALL DIETARY INTAKE

K. Duncanson¹, E. Hoedt¹, G. Williams¹, S. Keely¹, N.J. Talley¹

¹The University of Newcastle, College of Health, Medicine and Wellbeing, New Lambton Heights, Australia

Contact E-Mail Address: kerith.duncanson@newcastle.edu.au

Introduction: Limiting fermentable carbohydrates (FODMAPs) is an evidence-based irritable bowel syndrome (IBS) management approach and food antigen avoidance is common in IBS (1). The gut microbiota degrades undigested food and specific microbes may produce antigens that trigger IBS symptoms (2). Correlations between the gut microbiota and whole-of-diet intakes of specific microbiota-degradable food compounds and food antigens by people with IBS have not been elucidated.

Aims & Methods: The aim of this study was to compare dietary intakes and the gut microbiota of adults with IBS to healthy controls to inform personalised diet intervention-based research. This cross-sectional study used data and samples from a digestive health biobank. Demographic, psychological and symptom data were analysed against dietary data from a food frequency questionnaire (FFQ) and 24-hour diet recall (24-HR) aligned with biobanked stool samples. Dietary data were compared using

independent and paired t-tests. Stool sample gDNA was extracted using the Promega Maxwell DNA recovery system and shotgun metagenomic sequencing performed to a depth of 3Gb. Taxonomic profiling was completed with MetaPhlan4 and results analysed using R packages phyloseq, MicroEco and Maaslin2.

Results: Thirty-four adults with IBS (23 IBS-D, 11 IBS-C) and 39 healthy controls were included. Demographic and clinical characteristics were not significantly different between IBS and controls except for psychological distress ($p<0.001$), anxiety and depression ($p<0.05$) and gastrointestinal symptom burden ($p<0.001$). Usual dietary intake of participants with IBS was significantly lower than controls for total FODMAPs ($p<0.05$) and lactose (both $p<0.05$). In the 24-48 hours prior to stool sampling, participants with IBS consumed significantly lower total fibre ($p<0.01$), fruit serves ($p<0.01$) and gluten ($0<0.05$).

Energy, macro- and micronutrients did not differ between groups (FFQ or 24-HR) and were consistent between FFQ and 24-HR for most dietary variables. Microbial beta diversity differed between IBS and controls ($p<0.01$ PERMANOVA) and IBS-C and IBS-D subtypes ($p<0.001$). Microbiota profiles differed between IBS and controls. Two microbial species (sp.) were positively associated with gluten (24-HR) intake (1 unclassified Clostridia sp., 1 unclassified sp. from Actinomycetaceae family, both $p<0.01$) in the IBS cohort. Strong positive correlations were evident in controls for saturated fat (12 bacterial species, all $p<0.001$) and total energy (15 species, all $p<0.05$), with strong negative correlations evident between *Akkermansia muciniphila* and saturated fat ($p<0.001$), total energy ($p<0.01$), total fat, and caffeine (both $p<0.05$). Bacterial species with significant correlations to dietary variables across both usual and 24-HR dietary data were *Akkermansia muciniphila* and unclassified Firmicutes GGB14025.

Dietary intake	IBS (n=23) (past 12 months)	Controls (n=18) (past 12 months)	p-value	IBS (n = 30) (24 hour recall)	Control (n = 31) (24 hour recall)	p-value
Dietary fibre (grams/day)	32.0± 14.0	32.1±6.3	0.997	20.6±8.9	28.8±12.3	0.015*
Gluten (grams/day)	NA	NA	NA	10.94 (6.15)	7.5±4.5	0.030*
Total FODMAPs (grams/day)	22.8±14.3	33.6±18.9	0.049*	NA	NA	NA
Lactose (grams/day)	11.2±12.9	21.7±13.8	0.017*	14.3±13.9	17.4±9.6	0.311
Fruit (serves/day)	NA	NA	NA	0.87±0.7	1.6±1.2	0.009**

Conclusion: Microbiota differences between adults with IBS and controls were associated with diet and clinical characteristics. Differences in relationships between specific FODMAPs (lactose) and food antigens (gluten) and microbiota associations has clinical relevance for IBS dietary management.

Future translation-focussed research investigating personalisation of dietary intervention for microbiota-targeted symptom management in IBS is warranted.

RETHINKING THE REROUTING OF NASOJEJUNAL TUBE INSERTION: CONSIDERING PATIENT AND ENVIRONMENTAL FACTORS

S. Dimitriadis¹, P. Dahiya², K. Hamesch³, O. Cahyadi⁴

¹University Hospital Coventry and Warwickshire, Gastroenterology, Coventry, United Kingdom, ²University of Birmingham, Birmingham, United Kingdom, ³University Hospital Aachen, Gastroenterology, Aachen, Germany, ⁴St. Josef-Hospital, Hospital of the Ruhr-University-Bochum, Gastroenterology, Essen, Germany

Contact E-Mail Address: dimitriadis.stavros@yahoo.com

Introduction: Nasojejunal tubes (NJT) are usually inserted into the small intestine with the help of an endoscope, after which they need to be redirected through the nose. The current method of redirection involves using a rerouting tube, a laryngoscope, and forceps, which can be uncomfortable for patients due to the sensitivity of the throat. Besides, this method is resource-intensive and creates sustainability issues, as the instruments are mostly single-use and contain batteries. The National Health Service (NHS) accounts for 5.4% of UK carbon dioxide emissions, one which, in 2015, amounted to 26.6 million tonnes of carbon dioxide equivalent—equating to 39% of all public sector emissions in England. Endoscopy appears to be a significant contributor to health care's environmental footprint, generating about 3.09 kg of waste per bed per day (the third highest emitting hospital department).¹

Aims & Methods: We aimed to gather information on the standard practices related to NJT placement and understand the challenges faced by endoscopists and patients as perceived by practitioners such as nurses and endoscopists. For this purpose, we designed a short survey consisting of 16 questions on Survey Monkey. We shared the survey through various channels such as WhatsApp groups, X, and emails from gastroenterologists, endoscopists, and nurse groups. The survey remained open for 30 days and was shared globally.

Results: A total of 146 participants responded to the survey. The majority (73.9%) were from the UK, 13 % from Europe and the remaining from the rest of the world. The majority (88.4%) were medical endoscopists, with a median experience of 6 (1-30) years in NJT placement. The standard "through the scope" method was the preferred technique for NJT insertion (78.8%) of participants. Some (10.9%) preferred a slim scope through the nose and then placing NJT over a wire; others reported mixed methods, including under fluoroscopy guidance. Most respondents used midazolam and an opiate for the procedure (67.1%), only midazolam (13.7%), propofol (16.4%), and only a handful did it without sedation. The most challenging step reported by participants was the NJ tube rerouting from the mouth to the nose (41.7%), followed by avoiding displacement of the NJ tube during scope removal (27.4%). Redirection from the mouth to the nose was also considered the most uncomfortable step for patients, with 71.2% of participants, followed by oesophageal intubation (15.1%). Laryngoscopes were used as a light source during rerouting by 74.7%, out of which 45.9% used disposable laryngoscopes. Similarly, 80% of respondents used Magill's forceps, half of which were single-use. Notably, 80.8% of participants expressed concern about the environmental impact of single-use instruments in endoscopy.

Conclusion: This study highlights endoscopy practitioners' primary difficulties when performing NJ tube placement. Rerouting the tube from the mouth to the nose is considered the most challenging and uncomfortable

step for patients. The findings emphasise the urgency for improved techniques or equipment to address this challenge, reduce patient discomfort, and consider environmental sustainability in endoscopy.

BURIED BUMPER SYNDROME: A RETROSPECTIVE STUDY OF INTERVENTION SUCCESS

L. Herlihy¹, S. Taylor¹, C. Neelankavil¹, Z. Zeino²

¹North Bristol NHS Trust, Bristol, United Kingdom, ²North Bristol NHS Trust, Gastroenterology, Bristol, United Kingdom

Contact E-Mail Address: laura.herlihy@nbt.nhs.uk

Introduction: Buried bumper syndrome (BBS) is a complication of a percutaneous endoscopic gastrostomy (PEG) which occurs when the internal bumper migrates into the gastric wall. There are several techniques used to manage BBS. The Flamingo is a novel device specifically developed to release buried bumpers and was first used at North Bristol Trust (NBT) in 2018. This study compared the effectiveness of methods used to free buried bumpers before and after the introduction of this device.

Aims & Methods: The primary endpoint was to determine the success of the Flamingo device in resolving BBS compared to balloon dilatation, needle knife and surgical removal. Data was obtained retrospectively from single endoscopy unit study between January 2010 to July 2023. Due to low numbers, balloon dilatation and needle knife were grouped together for analysis. Additional outcome parameters were complication rate, site change and sedation. Baseline patient demographic and clinical parameters were compared between groups.

Results: Forty-three cases of BBS were identified where balloon/knife, Flamingo or surgery was used to free the buried bumper (median age, 59; 31 males (72.15%)). 20 BBS cases attended endoscopy prior to January 2018 with balloon/knife intervention successful in 11/16 patients (68.75%) and 4 successful surgical removals. After January 2018, balloon/knife interventions succeeded in 2/5 (40%), with subsequent successful surgical (n=1) or flamingo (n=2) interventions. Flamingo alone succeeded in 17/18 patients (94.4%). Combining all BBS cases, the overall success rate of Flamingo was 95% compared to 61.9% for balloon/knife ($P = .02$). Surgical removal success rate was 100%. Complication rate was highest post-surgical removal (60%) compared to Flamingo (20%) and balloon/knife (4.76%).

	Balloon/knife	Flamingo	Surgical
Initial intervention	21	18	4
Rescue intervention used	0	2	1
Success rate	61.9% (13/21)	95% (19/20)	100% (5/5)
Complication rate	4.76% (1/21)	20% (4/20)	60% (3/5)
New site	4	2	1
Same site, new tract	5	1	0
Sedation	1 GA	1 GA	5 GA

Conclusion: Removal of buried bumpers using the Flamingo device was significantly more successful than using the balloon/knife. All surgical procedures were prior to Flamingo or required to rescue balloon/knife. This means there needs to be investigations to determine whether the flamingo can obviate need for surgery and whether these two procedures cause an overall excess of complications.

Disclosure: No Conflict of Interest.

Contact E-Mail Address: dr.mahmoud.obeidat@gmail.com

Introduction: Despite a lack of evidence, patients are often not fed for 48 to 96 hours after upper gastrointestinal bleeding (UGIB); however, many trials have demonstrated the benefits of early nutrition (EN). We conducted a meta-analysis of randomized controlled trials (RCTs) to evaluate the outcomes of EN compared to delayed nutrition (DN) after UGIB.

Aims & Methods: The protocol was registered on PROSPERO (CRD42022372306). PubMed, Embase, CENTRAL, Scopus, and Web of Science were searched on the 27th of August 2023 to identify eligible RCTs. The primary outcomes were early (within 7 days) and late (within 30-42 days) mortality and rebleeding. Pooled risk ratios (RR), mean differences (MD), and corresponding 95% confidence intervals (CI) were calculated using a random-effects model.

Results: A total of 10 trials with 1,051 patients were included in the analysis. Early mortality was not significantly different between the two groups (RR: 1.20, CI: 0.85 – 1.71, $P = 0\%$), whereas late mortality was reduced to a clinically relevant extent in the EN group (RR: 0.61, CI: 0.35 – 1.06, $P = 0\%$). When comparing the two groups, we found no significant difference in terms of early and late rebleeding (RR: 1.04, CI: 0.66 – 1.63, $P = 0\%$ and RR: 1.16, CI: 0.63 – 2.13, $P = 0\%$, respectively). Our analysis also showed that the length of hospital stay was reduced in the EN group compared to the DN group (MD: - 1.22 days, CI: - 2.43 to - 0.01, $P = 94\%$).

Conclusion: Compared with DN, EN (within 24 hours) appears to be a safe intervention and could reduce the length of hospital stay without increasing the risk of complications after UGIB.

Introduction: Mirikizumab is a humanized immunoglobulin G4 monoclonal antibody against the p19 subunit of interleukin-23, a key inflammatory mediator in ulcerative colitis (UC). Mirikizumab demonstrated an acceptable safety profile, clinical response, clinical remission, and endoscopic remission in the pediatric SHINE-1 study.

Here we describe patient-reported outcomes in pediatric patients with moderate to severe UC from the phase 2 SHINE-1 study (NCT04004611) following 52 weeks of mirikizumab treatment.

Aims & Methods: Patients aged 2 to <18 years with active UC who had an inadequate response, loss of response, or intolerance to corticosteroids, immunosuppressants, or biologic therapies, or had corticosteroid-dependent colitis, were included in the study. Patients weighing >40 kg received an induction dose of mirikizumab 300 mg via intravenous infusion; patients weighing ≤40 kg received mirikizumab 5 or 10 mg/kg via intravenous infusion at weeks 0, 4, and 8. At week 12, patients were assessed for clinical response using the Modified Mayo Score. Responders entered a maintenance period and received subcutaneous doses of mirikizumab at 200 mg (>40 kg), 100 mg (>20 kg to ≤40 kg), or 50 mg (≤20 kg) once every 4 weeks, with the last patient visit at week 52. Abdominal Pain Numeric Rating Scale (NRS), Urgency NRS, and Fatigue NRS scores were assessed through 52 weeks.

Age Range, n	Change from Baseline at Week 52 (Responder population) (N=18) ^a		
	Abdominal Pain NRS Score ^b Mean (SD)	Urgency NRS Score ^c Mean (SD)	Fatigue NRS Score ^d Mean (SD)
2 to <8 years, n=2	-4 (2.8)	-4 (4.2)	-3 (2.8)
8 to <12 years, n=3	-2 (1.0)	-2 (1.5)	-2 (1.0)
12 to <18 years, n=11	-4 (2.5)	-5 (2.1)	-3 (2.0)

Abbreviations: n = sample population; NRS = numeric rating scale; SD = standard deviation.

aTwo patients did not have baseline data and were not included in this analysis.

bThe Abdominal Pain NRS measures the „worst abdominal pain in the past 24 hours“ using an NRS ranging from 0 to 5 (8 to 11 years old) and 0 to 10 (12 to 17 years old). For children less than 8 years old, caregivers completed an observer-reported instrument ranging from 0 to 10.

cThe Urgency NRS measures the severity of the urgency (sudden or immediate need) to have a bowel movement in the past 24 hours using an NRS ranging from 0 to 5 (8 to 11 years old) and 0 to 10 (12 to 17 years old). For children less than 8 years old, caregivers completed an observer-reported instrument ranging from 0 to 10.

dThe Fatigue NRS is a single item that measures the „worst fatigue“ (weariness, tiredness) in the past 24 hours using an NRS ranging from 0 to 5 (8 to 11 years old) and 0 to 10 (12 to 17 years old). For children less than 8 years old, caregivers completed an observer-reported instrument ranging from 0 to 10.

Table 1.

Results: Responders (69.2%, n=18/26) reported improvements in Abdominal Pain NRS, Urgency NRS, and Fatigue NRS scores through all age groups compared to baseline at week 52 (Table 1). A ≥30% improvement in the Abdominal Pain NRS was observed in 50% (n=7) of patients aged 12 to <18 years who scored ≥3 at baseline (N=14).

Conclusion: Mirikizumab demonstrated improvements in abdominal pain, bowel urgency, and fatigue following induction and maintenance treatment. These results provide supporting evidence for the pivotal phase 3 pediatric study SHINE-2 and suggest important improvements in quality of life.

Introduction: Corticosteroid (CS) chronic overuse is a concern in the treatment of Crohn's disease (CD), with adverse events and toxicities seen with the long-term use of CS resulting in increased follow-up morbidity and economic burden.^{1,2} Risankizumab (RZB) is an interleukin 23 p19 inhibitor that demonstrated efficacy for the treatment of moderately to severely active CD in phase 3 trials. Here, we report the results of a post

hoc analysis evaluating the ability of RZB to achieve corticosteroid-free outcomes in patients with CD enrolled in the FORTIFY open-label, long-term extension (LTE) substudy.

Aims & Methods: This analysis was designed to understand how effectively RZB can manage CD without the use of CS. The ongoing FORTIFY (NCT03105102) open-label, LTE substudy enrolled patients who entered the open-label extension trial after 52 weeks of RZB maintenance dosing. Patients received RZB 180 mg every 8 weeks, except for patients who had prior rescue therapy, who continued RZB 360 mg. Changes to CD-related CS dose were made at investigators' discretion. Prescheduled visits occurred every 24 weeks and endoscopies every 96 weeks. Baseline CS use was per induction baseline. Outcomes assessed among the overall population and patients with baseline CS use included mean time of CS use, median CS dose, and proportion of patients who achieved CS-free (ie, no CS use at evaluation) clinical remission, assessed by average daily stool frequency and abdominal pain score (SF/APS) and Crohn's Disease Activity Index (CDAI), endoscopic response, and endoscopic remission. Data are presented as observed for all patients and by nonresponder imputation for patients with 2 years of complete (matured) data.

Results: Of 1147 patients enrolled in the LTE study, 325 (28.3%) patients had baseline CS use. Overall, 143 of 1147 (12.5%) of patients received CS at any time during the LTE; median (IQR) time of CS use was 0.0 (0.0) days and median (IQR) CS dose was 0.0 (0.0) mg through data cutoff. Among 325 patients with baseline CS use, 79 received CS during the LTE for a median (IQR) of 138.0 (452.0) days. Among the 754 patients with 2-year matured data, 206 (27.3%) received baseline CS. For patients with 2-year matured data, CS-free clinical remission was demonstrated at week 48 and week 96 per SF/APS (overall, 50.1%, 43.9%; with baseline CS use, 39.8%, 38.3%) and CDAI (overall, 52.5%, 45.4%; with baseline CS use, 45.1%, 40.8%). At week 96 for patients with 2-year matured data, CS-free endoscopic response was achieved by 49.5% overall and 46.6% of patients with baseline CS use; 39.7% and 32.5% achieved CS-free endoscopic remission, respectively. As observed data are also presented (Table). Overall, CS-free clinical remission and CS-free endoscopic remission were maintained from week 0 to week 96 in 62.3% and 72.2% of patients with 2-year matured data.

AO, as observed; CDAI, Crohn's Disease Activity Index; NRI, nonresponder imputation; SES-CD, Simple Endoscopic Score for Crohn's Disease; SF/APS, stool frequency/abdominal pain score.
*Only patients with 2-year matured data are included in NRI analysis.
SF/APS clinical remission: Average daily SF ≤ 2.8 and not worse than baseline value and average daily APS ≤ 1 and not worse than baseline value.
CDAI clinical remission: CDAI < 150.
Endoscopic response: Decrease in SES-CD > 50% from baseline as scored by a central reviewer.
Endoscopic remission: SES-CD ≤ 4 and at least a 2-point reduction vs baseline and no subscore greater than 1 in any individual variable, as scored by a central reviewer.

Table. Corticosteroid-free Clinical and Endoscopic Outcomes With Risankizumab at Week 96 in the Overall Population and in Patients With Baseline Corticosteroid Use.

Conclusion: Long-term use of RZB in patients with moderately to severely active CD may achieve CS-free clinical remission, endoscopic response, and endoscopic remission. Additionally, a majority of patients did not add CS during the LTE. Thus, RZB may be used to support the reduction of CS in patients with CD.

Introduction: Symptomatic, endoscopic, and histological remission simultaneously, known as disease clearance (DC), has been proposed as an aspirational target in ulcerative colitis (UC). [1, 2] Mirikizumab (miri), an anti-IL-23p19 antibody, has demonstrated strong efficacy as shown by single and combined clinical endpoints in LUCENT Phase 3 trials. [3-5] This analysis evaluated the impact of miri on DC during LUCENT-1 (NCT03518086), LUCENT-2 (NCT03524092) and long-term LUCENT-3 (NCT03519945) trials and the association between DC and other clinical and patient-reported outcomes (PROs).

Aims & Methods: DC is defined as symptomatic remission [Mayo stool frequency (SF)=0, 1 with a ≥ 1 point decrease from baseline + rectal bleeding (RB)=0], and histologic-endoscopic mucosal remission [HEMR: Mayo endoscopic remission (ER: endoscopy subscore of 0 or 1, excluding friability) + Geboes score ≤ 2 B.0]. PROs of interest included Fatigue NRS, IBDQ remission, SF-36, WPAI:UC, PGRS, and PGRC (see table footer). Clinical outcomes include clinical remission, corticosteroid-free remission, ER, HEMR, bowel urgency (BU) remission, SF remission, and RB remission. [2,5] The proportion of patients achieving DC was assessed at W12, W52, and W104. Treatment comparisons were made using a CMH test adjusting for randomization factors. Associations between the PROs and DC were evaluated at W12 and W52 in miri-treated patients.

The associations between clinical outcomes and early achievement of DC in miri-treated patients at W12 and W52 were evaluated at W52 and W104, respectively. Non-responder imputation was used for all analyses.

Results: A significantly higher proportion of miri-treated patients achieved DC vs PBO at W12 [N=868 miri, 294 PBO] (DC: 16.0% vs 7.1%, $p<0.0001$) and W52 [N=365 miri, 179 PBO] (DC: 36.4% vs 19.6%, $p=0.0002$). Similar trends were seen for biologic failure subgroups at W12 (bio/JA-Ki-failed: [n=361 miri, 118 PBO; DC: 9.1% vs 5.9%]; bio/JAKi-naïve: [n=492 miri, 171 PBO; DC: 20.9% vs 7.6%]) and W52 (bio/JAKi-failed: [n=128 miri, 64 PBO; DC: 31.3% vs 12.5%]; bio/JAKi-naïve: [n=229 miri, 114 PBO; DC: 39.3% vs 23.7%]). At W104 (N=239 miri), 40.6% of patients achieved DC with 2-year treatment with miri. Specifically, 38.4% of bio/JAKi-failed (n=73) and 40.9% of bio/JAKi-naïve (n=159) patients achieved DC. Significantly greater improvement in all PROs was seen at W12 for patients who achieved DC vs those who did not at W12 in miri-treated patients. Similar associations were observed at W52, except in WPAI:UC overall work productivity (Table 1A). Patients achieving DC at W12 were more likely to achieve all clinical outcomes, except BU remission, at W52 versus those who did not achieve DC at W12. This trend was repeated in patients who achieved DC at W52 and continued to W104 (Table 1B).

Conclusion: Miri consistently demonstrated DC across induction, maintenance, and long-term studies. Over 36% of patients achieved DC after one year of miri treatment. The attainment of DC was associated with improvement in PROs in LUCENT-1 and -2. Early achievement of DC was associated with better long-term clinical outcomes.

Note: * $p<0.05$; ** $p<0.01$; *** $p<0.001$.

DC = Symptomatic Remission & HEMR.

Fatigue Numeric Rating Scale (NRS) is a single item patient-reported outcome measure that assesses fatigue on an 11-point NRS scale ranging from 0 (no fatigue) to 10 (fatigue as bad as you can imagine).

Inflammatory Bowel Disease Questionnaire (IBDQ) = A 32-item patient-completed questionnaire that assesses four domains of IBD-related quality of life: "Bowel Symptoms", "Systemic Symptoms", "Emotional Function", and "Social Function". A higher total score of all 32-items combined indicates better IBD-related quality of life. An IBDQ score equal or greater than 170 points has been suggested for disease remission.

Medical Outcomes Study 36-Item Short Form Health Survey Version 2 Standard (SF-36) = a 36-item patient-reported outcome measure designed to assess health-related quality of life in eight domains: physical functioning, role-physical, role-emotional, bodily pain, vitality, social functioning, mental health, and general health. The mental and physical well-being domains ladder to the Mental Component Summary (MCS) score and the Physical Component Summary (PCS) score. The MCS and PCS summary scores range from 0 to 100, where higher scores indicate better levels of function and/or better health.

WPAI:UC = Work Productivity and Activity Impairment Questionnaire-Ulcerative Colitis (WPAI:UC) is a 6-item patient-reported outcome measure that assesses UC-related impairment of daily activity and work productivity over the past 7 days. Scores are represented as impairment percentages, with higher numbers indicating greater impairment and less productivity. (change from baseline)

PGRS = A 1-item patient-rated questionnaire designed to assess the patients' rating of their disease symptom severity over the past 24 hours. Responses are graded on a 6-point scale in which a score of 1 indicates the patient has no symptoms (that is, "none") and a score of 6 indicates that the patient's symptom(s) are "very severe."

PGRC = A patient-rated instrument designed to assess the patients' rating of change in their symptom(s). Responses are graded on a 7-point Likert scale in which a score of 1 indicates that the subject's symptom(s) is "very much better," a score of 4 indicates that the subject's symptom has experienced "no change," and a score of 7 indicates that the subject's symptom(s) is "very much worse."

Symptomatic remission = MMS SF=0 or SF = 1 with a ≥ 1 point decrease from baseline and RB = 0.

HEMR = endoscopic remission (MMS ES = 0 or 1 (excluding friability)) and a Geboes subscore of 0 for grades 2b (lamina propria neutrophils), 3 (neutrophils in epithelium), 4 (crypt destruction), and 5 (erosion or ulceration).

Clinical remission = MMS SF = 0 or 1 with a ≥ 1 point decrease from baseline, RB = 0, and ES = 0 or 1 (excluding friability).

CS-free remission = At LUCENT-2 W40 (W52 of continuous treatment), clinical remission at W40, symptomatic remission at W28, and no CS use for ≥ 12 weeks prior to W40. At LUCENT-3 W52 (W104 of continuous treatment), corticosteroid-free remission is defined as clinical remission at W52 and no corticosteroid use for at least 12 weeks prior to W52.

Endoscopic remission = MMS ES = 0 or 1 (excluding friability).

BU remission = Urgency NRS Score = 0 or 1.

SF remission = MMS SF=0, or SF=1 with a ≥ 1 -point decrease from induction baseline.

RB remission = MMS RB=0.

Associations between DC and categorical outcomes were analyzed using a CMH test adjusted for randomization factors, and corresponding odds ratios were determined. Non-responder imputation was used to impute missing values. For continuous outcomes, associations were analyzed using analysis of covariance with mBOCF using a model that included baseline outcome value and randomization factors. Relative effect sizes were determined.

Abbreviations:

BU = Bowel Urgency; CS = corticosteroid; CMH = Cochran-Mantel-Haenszel; HEMR = histologic-endoscopic mucosal remission; IBDQ = inflammatory bowel disease questionnaire; LSM = least squares mean; MCS = mental component score; MMS = modified Mayo score; N = number of patients in the analysis population; n = number of patients in the specified category; NRS = numeric rating scale; PCS = physical component score; PGRC = patient global rating of change; PGRS = patient global rating of severity; RB = Rectal Bleeding; SF = Stool Frequency; SF-36 = 36-item short-form health survey; std = standard error; UNRS = Urgency Numeric Rating Scale; W = week; mBOCF = modified baseline observation carried forward; WPAI = work productivity activity impairment questionnaire.

Introduction: Mirikizumab (miri), an anti-IL-23p19 antibody, has demonstrated efficacy and safety in moderately to severely active ulcerative colitis (UC) Phase 3 trials (LUCENT-1 and -2; NCT03518086, NCT03524092) among patients who had an inadequate response, loss of response, or intolerance to conventional or advanced therapy. At the LUCENT-1 induction baseline, 41% of the population had experienced a biologic/tofacitinib failure, and 36.3% experienced at least one anti-TNF failure. Among patients with one prior anti-TNF failure only, this analysis evaluated the clinical efficacy of miri compared to placebo (PBO) in induction and maintenance therapy and the efficacy of miri in extended induction.

Aims & Methods: In LUCENT-1, UC patients were randomized to receive 3 intravenous (IV) doses of 300mg miri or PBO every four weeks (Q4W) at W0, W4, and W8 (induction population). In LUCENT 2, responders to miri induction at W12 were re-randomized to subcutaneous (SC) 200mg miri or PBO Q4W through W52 of continuous therapy (maintenance population). Patients not achieving clinical response with miri 300mg IV at W12 received extended induction treatment with open-label 300mg miri IV at W12, W16, and W20 (extended induction population). Patients responding to extended induction at W24 entered open-label maintenance and received 200mg miri Q4W SC until W52 (extended induction responders). Endpoints evaluated were clinical response, clinical remission, symptomatic remission, endoscopic remission, corticosteroid (CS)-free remission, and histologic-endoscopic mucosal remission (HEMR). Efficacy in the subgroup of patients with failure of one anti-TNF only was assessed using Cochran-Mantel-Haenszel tests at W12 (induction population) and W52 (maintenance population).

Results: At LUCENT-1 baseline, of patients who experienced anti-TNF failure, 45% of patients (n=190) had one prior anti-TNF failure only. The one anti-TNF failure subgroup had a longer disease duration, higher rate of pancolitis, similar disease severity (MMS and ES) and slightly higher baseline CS and IMM use, compared to the overall LUCENT population. In the induction and maintenance population, a significantly greater proportion of miri-treated patients achieved the following efficacy endpoints compared with PBO [miri vs. PBO, p-value]: clinical response (W12: [64.4% vs. 34.1%, p=0.001]; W52: [67.2% vs. 44.8%, p=.03]), clinical remission (W52: [44.3% vs. 17.2%, p=.017]), symptomatic remission (W52: [63.9% vs. 34.5%, p=.005]) (Table). Among the extended induction population, 45.7% achieved clinical response at W24; 75% achieved clinical response, 30% achieved clinical remission and CS-free remission at W52 (Table).

	LUCENT-1 W12 (Induction Population)				LUCENT-2 W52 (Maintenance Population)			
	PBO IV n (%)	300mg Miri IV n (%)	p-value ^b	Risk Difference (95% CI) ^c	PBO SC n (%)	200mg miri SC n (%)	p-value ^b	Risk Difference (95% CI) ^d

[a] modified-Intent-To-Treat population, non-responder imputation.

[b] Cochran-Mantel-Haenszel (CMH) test adjusted by corticosteroid use (yes/no) at AMAN baseline, region (North America/Europe/Other), Clinical Remission status (yes/no) at AMAN Week 12. **Statistically significant p-values are bolded.**

[c] The common risk difference is the difference in proportions adjusted for the stratification factor(s): baseline corticosteroid use (yes/no), baseline disease activity (MMS: [4-6] or [7-9]), and region (North America/Europe/Other), where the confidence intervals are calculated using Mantel-Haenszel-Sato method.

[d] Risk difference based on difference in proportions adjusted for the stratification factor(s): corticosteroid use (yes/no) at LUCENT 1 baseline, region (North America/Europe/Other), Clinical Remission status (yes/no) at LUCENT 1 Week 12, where the confidence intervals are calculated using Mantel-Haenszel-Sato method.

IV = intravenous; miri = Mirikizumab, PBO = placebo; SC = subcutaneous; TNF = tumor necrosis factor; CS = corticosteroid. Clinical response = decrease in the modified Mayo score of ≥ 2 points and $\geq 30\%$ decrease from baseline (BL), and decrease of ≥ 1 point in the rectal bleeding (RB) subscore from BL or an RB score of 0 or 1. Clinical remission = Stool frequency (SF) = 0, or SF = 1 with a ≥ 1 -point decrease from baseline; rectal bleeding (RB) = 0; endoscopic subscore (ES) = 0 or 1 (excluding friability). Endoscopic remission = Mayo endoscopic subscore = 0 or 1 (excluding friability). Symptomatic Remission = stool frequency (SF) = 0, or SF = 1 with a ≥ 1 -point decrease from baseline and rectal bleeding = 0. CS Free Remission = Clinical remission at Week 40, symptomatic remission (SF = 0, or SF = 1 with a ≥ 1 -point decrease from induction baseline; and RB=0) at Week 28, and no corticosteroid use for ≥ 12 weeks prior to Week 40. HEMR = histologic-endoscopic mucosal remission, histologic remission with resolution of mucosal neutrophils, determined by Geboes $\leq 2B.0$ score.

Table: Efficacy of miri vs PBO for subjects with Only One Prior anti-TNF Failure^a

Conclusion: Mirikizumab is efficacious for induction and maintenance therapy in patients with moderately to severely active UC who have failed one prior anti-TNF.

Introduction: Mirikizumab, a p19-directed interleukin-23 monoclonal antibody, is efficacious in inducing clinical remission at Week (W) 12 and maintaining clinical remission through W52 and W104 in patients with moderately-to-severely active ulcerative colitis (UC) (LUCENT-1, NCT03518086; LUCENT-2, NCT03524092; LUCENT-3, NCT03519945).

Here we present efficacy and safety results through W152 of mirikizumab treatment from the open-label extension LUCENT-3 study.

Aims & Methods: Symptomatic, clinical, endoscopic, histologic, quality-of-life, and adverse event (AE) outcomes are reported for mirikizumab induction responders, including biologic failed patients, who entered the LUCENT-3 study, with data shown for W52 maintenance responders or remitters. Discontinuations or missing data were handled by nonresponder imputation (NRI), modified NRI (mNRI), and observed case (OC). mNRI uses multiple imputation for missing data and balances bias of NRI and OC. Table 1 provides endpoint and population definitions and abbreviations.

Results: Using mNRI, among W52 mirikizumab responders, 82% demonstrated clinical response at W152. Remission rates at W152 for W52 clinical responders were 56% clinical, 55% corticosteroid-free (CSF), 61% endoscopic, 53% histologic-endoscopic mucosal remission (HEMR), 75% symptomatic, and 59% bowel urgency.

Patients achieving histologic-endoscopic mucosal improvement (HEMI) and bowel urgency clinically meaningful improvement (CMI) at W152 were 53% and 74%, respectively. For W52 mirikizumab remitters, 85% demonstrated clinical response at W152. Remission rates at W152 for W52 clinical

remitters were 70% clinical, 69% CSF, 72% endoscopic, 63% HEMR, 81% symptomatic, and 61% bowel urgency. Patients achieving HEMI and bowel urgency CMI at W152 were 64% and 76%, respectively. Biologic Failed/Not Biologic Failed subgroup data demonstrate maintenance of efficacy (Table 1).

Endpoints at Week 152	In Week 52 Responders ¹ n=286 % All (95% CI) ³	In Week 52 Responders ¹ n=195 % Not Biologic Failed (95% CI) ³	In Week 52 Responders ¹ n=91 % Biologic Failed (95% CI) ³	In Week 52 Remitters ² n=179 % All (95% CI) ³	In Week 52 Remitters ² n=120 % Not Biologic Failed (95% CI) ³	In Week 52 Remitters ² n=59 % Biologic Failed (95% CI) ³

Bowel urgency CMI¹²

Abbreviations: CI=confidence interval; CMI=clinically meaningful improvement; CSF=corticosteroid-free; ES=endoscopic subscore; HEMI=histologic-endoscopic mucosal improvement; HEMR=histologic-endoscopic mucosal remission; MMS= Mayo Modified Score; mNRI=modified NRI; n=number of participants in the specific category; N=number of participants in the analysis population; NRI=nonresponder imputation; NRS=numeric rating scale; OC=observed case; RB=rectal bleeding; SF=stool frequency; UC=ulcerative colitis; UNRS=Urgency Numeric Rating Scale.

Definitions: Biologic Failed: Inadequate response, loss of response, or intolerant to a biologic therapy or the Janus kinase inhibitors for UC. Cerebrocardiovascular events: atrial fibrillation (N=2), angina unstable (N=1), coronary arterial stent insertion (N=1), hypertensive crisis (N=1), ventricular tachycardia (N=1) – angina and stent were same patient. Not Biologic Failed: failed conventional treatments (i.e., immunomodulators/corticosteroids); may include some participants who were exposed to but did not fail biologic treatment. Malignancy: thyroid cancer metastatic (N=1). mNRI (text): patients who discontinue treatment treated as nonresponders and patients who are otherwise missing endpoint data imputed using multiple imputation. NRI (table): patients who discontinue treatment treated as nonresponders and patients who are otherwise missing endpoint data tagged as nonresponders. OC (referred to): patients who discontinue treatment or are otherwise missing data are excluded from analyses. Opportunistic infection: herpes zoster (N=4), candidiasis (N=3) – one patient had each. ¹Responders: ≥30% and 2-point decrease from baseline in the composite clinical endpoint of the summary of ES, SF, and RB subscores, and RB=0 or 1, or ≥1-point decrease from baseline.

²Remitters: (MMS SF=0 or SF=1 with ≥1-point decrease from baseline; RB=0; ES=0 or 1) cohort of LUCENT-2 at Week 52.

³Response confidence interval: constructed using Wilson method, without continuity correction.

⁴Clinical response: ≥2-point and ≥30% decrease in MMS from baseline; RB=0 or 1, or RB ≥1-point decrease from baseline.

⁵Clinical remission: SF=0 or SF=1 with ≥1-point decrease in MMS from baseline; RB=0; ES=0 or 1 (excluding friability).

⁶Symptomatic remission: SF=0 or SF=1 with ≥1-point decrease in MMS from baseline; RB=0.

⁷CSF remission: clinical remission, and no corticosteroid use for at least 12 weeks prior to Week 52; SF=0 or SF=1 with a ≥1-point decrease from induction baseline; RB=0; ES=0 or 1 (excluding friability).

⁸HEMR: ES=0 or 1 (excluding friability) + Geboes ≤2.0.

⁹Endoscopic remission: ES=0 or 1 (excluding friability); score ranges 0 to 4; a lower score indicates less mucosal damage.

¹⁰HEMI: ES=0 or 1 (excluding friability) + Geboes ≤3.1.

¹¹Bowel urgency remission: UNRS=0 or 1 (Dubinsky MC, et al. J Patient Reported Outcomes 2022;6(1):1–15).

¹²Bowel urgency CMI: change from baseline in UNRS ≥3 in patients with UNRS ≥3 at induction baseline (Dubinsky MC, et al. J Patient Reported Outcomes 2022;6(1):1–15).

¹³In patients who had UNRS ≥3 at induction baseline.

Stool frequency, rectal bleeding, bowel urgency, and abdominal pain symptom score reductions from induction baseline at W52 were sustained through W152. Severe AEs were reported in 7.4% of patients, while 5.3% discontinued treatment due to an AE. AEs of special interest included opportunistic infection (1.8%), cerebrocardiovascular events (1.5%), and malignancy (0.3%). Elevated liver enzymes ≥3 upper limit of normal (ULN)

included alanine aminotransferase (0.9%), aspartate aminotransferase (1.2%); 2xULN total bilirubin (1.8%), alkaline phosphatase (0.6%), gamma-glutamyltransferase (2.9%); ≥ 5 ULN: AST (0.3%).

Conclusion: Symptomatic, clinical, endoscopic, histologic, and quality-of-life outcomes support the long-term sustained benefit of mirikizumab treatment up to 152 Wks in patients with UC, including biologic failed patients, with no new safety concerns.

Introduction: Mirikizumab (miri), an anti-IL-23p19 antibody, demonstrated robust efficacy in improving clinical, endoscopic, and inflammatory biomarker endpoints, and an acceptable safety profile for patients with moderately to severely active Crohn's disease (CD) in the Phase 3 VIVID-1 study. Here, we investigate the onset of symptomatic improvement and the safety of miri as induction therapy through Week 12 (W12) for patients with moderately to severely active CD.

Aims & Methods: In VIVID-1 (NCT03926130), patients (N=1065) had moderately to severely active CD (unweighted daily average stool frequency (SF) ≥ 4 [loose and watery stools defined as Bristol Stool Scale Category 6 or 7] AND/OR unweighted daily average abdominal pain (AP) ≥ 2 at baseline) and had prior failure to biologic and/or conventional therapy. Patients were randomized in a 6:3:2 ratio to receive miri (a single 900mg intravenous (IV) dose at W0, W4, and W8 followed by a subcutaneous (SC) dose of 300mg at W12 and then every 4 weeks), ustekinumab (uste) (6mg/kg IV at W0 and SC dose of 90mg at W8 and then every 8 weeks), or placebo (PBO). Results for the co-primary endpoints and major secondary endpoints versus PBO, as well as for the 2 major secondary endpoints versus uste, have been reported previously^{1,2}. This analysis focuses on comparisons of clinical response by Patient Reported Outcome (PRO) (defined as at least a 30% decrease in SF and/or AP with neither score worse than baseline), clinical remission by PRO (defined as SF ≤ 3 and not worse than baseline [as per Bristol Stool Scale Category 6 or 7] and AP ≤ 1 and no worse than baseline), change from baseline (CFB) in SF, and CFB in AP up to W12 in patients who were randomized to miri or PBO.

Results: Baseline characteristics were balanced across the miri (N=579) and PBO (n=199) treatment groups¹. Compared to PBO, a greater proportion of patients on miri achieved clinical response by PRO at W4, 6, 8, and 12, and clinical remission by PRO at W6, 8, and 12. Treatment with miri resulted in significant improvements in SF at W6, 8, and 12, and in AP at W4, 6, 8, and 12 when compared to PBO (Table 1). The overall safety was consistent with the known safety profile of miri. The most common treatment-emergent adverse events (TEAEs) during induction period in miri-treated patients were COVID-19, anaemia and headache. There were lower frequencies of SAEs (miri: 5.9%, PBO: 9.0%) and discontinuations due to adverse events (miri: 2.4%, PBO: 4.7%) in miri-treated patients versus PBO. There were no malignancies, no MACes, no Hy's law cases or deaths in the miri arm up to W12. One death was reported in the induction period in the PBO group.

	Clinical response by PRO ^a n (%)		Clinical remission by PRO ^a n (%)		Stool Frequency (CFB) ^b LSM (SE)		Abdominal Pain (CFB) ^b LSM (SE)

Footnotes: ^aNonresponder imputation was used. ^bModified baseline observation carried forward was used.
* refers to $p < 0.05$ significance; ** refers to $p < 0.01$ significance; *** refers to $p < 0.001$ significance; **** refers to $p < 0.0001$ significance
Abbreviations: AP=abdominal pain; CDAI= Crohn's Disease Activity Index; CFB=change from baseline;
PRO=Patient Reported Outcome (2 of the patient-reported items of the CDAI, AP and SF); LSM=least square mean; SE=standard error; SF=stool frequency; miri=mirikizumab; PBO=placebo

Conclusion: In patients with moderately to severely active CD, miri induction was associated with higher rates of clinical response and greater improvement in AP as early as W4, and higher rates of clinical remission and greater improvement in SF as early as W6 versus PBO. Increasing treatment effect was observed through W12. The safety of miri induction therapy was consistent with its known favourable safety profile.

Introduction: Ulcerative colitis (UC) is associated with symptoms that may considerably impair patients' health-related quality of life (HRQoL). Long-term treatment goals established in STRIDE-II include the recuperation of HRQoL in patients with active UC.¹

This post-hoc analysis evaluated the impact of Risankizumab (RZB) as induction and maintenance therapy on normalisation of HRQoL in patients with moderate to severe UC.

Aims & Methods: This study evaluated data from two double-blind, Phase 3 trials, INSPIRE (induction: NCT03398148) and COMMAND (maintenance: NCT03398135). During induction, patients were randomised 2:1 to receive intravenous (IV) RZB 1200 mg or placebo (PBO) at Weeks 0, 4, and 8. Those with a clinical response based on Adapted Mayo score were randomised 1:1:1 to subcutaneous (SC) RZB 180 mg, RZB 360 mg, or PBO (RZB withdrawal) every 8 weeks for 52 weeks of maintenance. The proportion of patients achieving normalisation of individual HRQoL outcomes, per literature-based normative value threshold, was assessed at baseline and Weeks 12 and 52: FACIT-Fatigue score; IBDQ score; WPAI-UC (overall work impairment, work time missed, impairment while working, activity impairment); SF-36 PCS; SF-36 MCS; EQ-5D-5L VAS; and EQ-5D-5L index. A composite endpoint was determined to evaluate patients achieving normalisation of all HRQoL outcomes. Adjusted treatment differences between RZB and PBO were analysed using Mantel-Haenszel common rate difference. P values were calculated using Cochran-Mantel-Haenszel test and adjusted for strata.

Results: At Week 12, for RZB 1200 mg IV (n=650) vs PBO (n=325), more patients achieved normalisation of each individual HRQoL outcome (p<0.01) (Table 1). For RZB SC 180 mg (n=179) and 360 mg (n=186), more patients achieved normalisation of FACIT-fatigue, IBDQ, and SF-36 PCS vs PBO at Week 52 (p<0.05). More patients also achieved normalisation of all WPAI-UC scores with RZB 180 mg SC vs PBO (p<0.05), excluding overall work impairment. For SF-36 MCS and both EQ-5D-5L scores, more patients achieved normalisation with RZB 180 mg SC vs PBO (p<0.05), but not with RZB 360 mg SC. Normalisation of the composite HRQoL score

was achieved by more patients with all doses of RZB vs PBO at Weeks 12 (RZB 1200 mg: 12.5%; PBO: 4.9%) and 52 (RZB 360 mg: 20.4%; RZB 180 mg: 21.2%; PBO: 10.9%) (p<0.05).

*p<0.05. **p<0.01. ***p<0.001. ^aInduction: PBO IV, N=202; RZB 1200 mg IV, N=415. ^bMaintenance: PBO (withdrawal) SC, N=114; RZB 180 mg SC, N=114; RZB 360 mg SC, N=112. ^cProportion of patients achieving FACIT-F score ≥40.1, IBDQ score ≥170, 0% for WPAI-UC Daily Activity Impairment, SF-36 PCS ≥50 and MCS ≥50, EQ-5D-5L VAS ≥80.0 and EQ-5D-5L Index ≥0.825; employment-related scores were excluded.

For induction data, the Cochran-Mantel-Haenszel test was used to calculate p values and was adjusted for strata: Advanced Therapy-IR status (yes vs no), baseline steroid use (yes vs no), and baseline Adapted Mayo score (<=7 vs >7).

For maintenance data, the Cochran-Mantel-Haenszel test was used to calculate p values and was adjusted for strata: induction baseline Advanced Therapy-IR status (yes vs no), clinical remission status per Adapted Mayo score at Week 0 (per central read) (yes vs no) and last IV RZB induction dose (600 mg vs 1200 mg vs 1800 mg).

For induction and maintenance data, Mantel-Haenszel common rate difference was used to calculate adjusted treatment differences and 95% CIs.

CI, confidence interval; diff., difference; EQ-5D-5L, European Quality of Life 5 Dimensions 5 Levels; FACIT-F, Functional Assessment of Chronic Illness Therapy-Fatigue; HRQoL, health-related quality of life; IBDQ, Inflammatory Bowel Disease Questionnaire; imp., impairment; IR, inadequate response; IV, intravenous; MCS, Mental Component Summary; PBO, placebo; PCS, Physical Component Summary; RZB, risankizumab; SC, subcutaneous; SF-36, Short Form 36; UC, ulcerative colitis; VAS, visual analogue scale; WPAI, Work Productivity and Activity Impairment Questionnaire. <=

Table 1. Proportion of patients with UC achieving normalisation of HRQoL outcomes after treatment.

Conclusion: RZB shows greater normalisation of HRQoL compared to PBO, with results seen early during induction and subsequently continued through maintenance. These results indicate that the long-term treatment goal of HRQoL normalisation in patients with moderately to severely active UC may be achievable with RZB.

Introduction: The efficacy and safety of risankizumab (RZB), an anti-interleukin 23p19 monoclonal antibody, as induction and maintenance therapy for adults with moderately to severely active ulcerative colitis (UC) was recently reported.^{1,2} Influences of baseline disease characteristics on clinical outcomes are important to consider when optimizing UC treatment. Herein we analyze the efficacy of RZB stratified by baseline UC disease characteristics.

Aims & Methods: In the 12-week phase 3 INSPIRE induction study (NCT03398148) patients with moderately to severely active UC were randomized 2:1 to receive intravenous (IV) RZB 1200 mg or placebo (PBO) at weeks 0, 4, and 8. Patients with clinical response to RZB IV induction at

week 12 or 24 in the phase 2b/3 induction studies were randomized 1:1:1 to receive subcutaneous (SC) RZB 180 mg, RZB 360 mg, or PBO (RZB withdrawal) every 8 weeks in the 52-week phase 3 COMMAND maintenance study (NCT03398135). This post hoc analysis evaluates clinical response, clinical remission, endoscopic remission, endoscopic improvement, and histological-endoscopic mucosal improvement (HEMI) at week 12 and 52 in subgroups stratified by baseline disease characteristics (Adapted Mayo score, pancolitis, high-sensitivity C-reactive protein [hs-CRP], Mayo endoscopic subscore [ES], and disease duration).

AMS, Adapted Mayo score; ES, endoscopic subscore; hs-CRP, high-sensitivity C-reactive protein; IV, intravenous; PBO, placebo; RBS, rectal bleeding subscore; RZB, risankizumab; SC, subcutaneous; SFS, stool frequency subscore. Data are reported using nonresponder imputation while incorporating multiple imputation to handle missing data due to COVID-19 or the geo-political conflict in Ukraine and surrounding impacted regions. Clinical response is defined as a decrease in AMS that is ≥ 2 points and $\geq 30\%$ from baseline plus a decrease in RBS ≥ 1 or an absolute RBS ≤ 1 . Clinical remission is defined as SFS ≤ 1 (and not greater than baseline), RBS = 0, and endoscopic subscore ≤ 1 without evidence of friability.

Table. Clinical Response and Clinical Remission by Baseline Disease Characteristics.

Results: The induction analysis included 650 and 325 patients who received RZB 1200 mg IV and PBO IV, respectively. The maintenance analysis included 179, 186, and 183 patients who received RZB 180 mg SC, RZB

360 mg SC, and PBO (RZB withdrawal) SC, respectively. At induction week 12, the proportions of patients receiving RZB 1200 mg IV who achieved clinical response were numerically higher for the following baseline characteristic subgroups: pancolitis absence (70.5%) vs pancolitis presence (58.4%), Mayo ES of 2 (75.5%) vs Mayo ES of 3 (59.0%), and hs-CRP ≤ 5 mg/mL (68.9%) vs hs-CRP > 5 mg/mL (57.3%); the proportions of patients receiving RZB 1200 mg IV who achieved clinical remission at induction week 12 were also numerically higher for subgroups with pancolitis absence (25.3%) vs pancolitis presence (15.6%), Mayo ES of 2 (31.7%) vs Mayo ES of 3 (14.9%), and hs-CRP ≤ 5 mg/mL (23.7%) vs hs-CRP > 5 mg/mL (14.5%; Table). Differences in outcomes were not observed between subgroups stratified by Adapted Mayo score or disease duration. At week 52 of the maintenance study, there was no impact of baseline disease characteristics on achievement of clinical response and clinical remission with RZB (Table).

Conclusion: RZB induction and maintenance therapy improved clinical outcomes, regardless of baseline disease characteristics. Numerically higher RZB induction efficacy was observed for patients with no baseline pancolitis, Mayo ES of 2, and hs-CRP ≤ 5 mg/L. These trends are consistent with prior observations that patients with milder UC disease phenotypes tend to be more responsive to therapy.

Introduction: Risankizumab is a selective IL23 inhibitor that was approved by the FDA for the treatment of moderately to severely active Crohn's disease (CD) in June 2022. The effectiveness of risankizumab in ustekinumab-experienced patients is of particular interest due to a similar mechanism of action. Here, we present our one-year experience of risankizumab treatment in CD patients, with a focus on the comparison between ustekinumab-naïve and ustekinumab-experienced patients.

Aims & Methods: We prospectively followed patients with CD treated with risankizumab in our center and documented their clinical disease activity using Harvey-Bradshaw Index (HBI) score at baseline and at weeks 12, 26, and 52 after treatment initiation. We included patients who were treated for active luminal disease, defined as HBI ≥ 5, fecal calprotectin (FCP) ≥ 250, steroid dependence or who had evidence of active disease per ileocolonoscopy or imaging in the effectiveness analysis. We excluded from the effectiveness cohort patients with ileostomy, J-pouch or surgery within the 6 months prior to risankizumab commencement. We recorded adverse events in all patients. Patients who stopped treatment due to ineffectiveness or intolerance were counted as non-responders for the purpose of remission-rate calculations at each time point.

Characteristic	All patients (n=253)	Patients in the effectiveness cohort (n=153)
Age, y, median (IQR)	42 (30-54)	41.5 (30.25-54)
Disease duration y, median (IQR)	14 (9-22)	12 (8-22.75)
Female sex, n (%)	151 (60.9)	89 (58.2)
White race	198 (80.2)	116 (75.8)
Smoking history, n (%)		
current	13 (5.3) 56 (23)	10 (6.6) 38 (25)
former		
Baseline HBI, median (IQR)	5 (2-8)	5.5 (3-9)
Advanced therapy naïve n (%)	28 (11)	14 (9.1)
History of bowel resection, n (%)	158 (65)	89 (59.3)
Steroid treatment at baseline, n (%)	61 (29)	48 (33.6)

Results: 253 patients were treated with risankizumab and had at least 12 weeks of follow up. 153 patients were included in the effectiveness cohort. Demographics and patient characteristics are detailed in Table 1. At week 12, 71.3% (92/129) achieved clinical remission (CR), and 63.6% (82/129) achieved steroid-free clinical remission (SFCR). At week 26, 64.5% (60/93) and 62.4% (58/93) achieved CR and SFCR respectively. At 1 year, CR rate was 53.3% (40/75), and SFCR rate was 48% (36/75). Median FCP was 385.5µg/g (IQR 168.25-905, n=33) at baseline, 102.5µg/g (IQR 39-354, n=20) at week 12, 118µg/g (IQR 40-183, n=24) at week 26, and 63µg/g (IQR 19-122, n=16) at 1 year. 79.6% (74/93) remained on risankizumab 6 months after treatment initiation, and 64.3% (52/75) of patients remained on treatment at one year. In the effectiveness cohort, 47.7% (73/153) of patients were ustekinumab-naïve, and 53.3% (80/153) were ustekinumab-experienced. SFCR rates in ustekinumab-naïve and ustekinumab-experienced patients were 73.8% (45/61) vs. 54.4% (37/68) at week 12 (p=0.0282), 67.4% (31/46) vs. 57.4% (27/47) at week 26 (p=0.3936), and 54.1 (20/37) vs. 42.1% (16/38) at one year (p=0.3588), respectively.

Minor adverse events were documented in 12.6% (32/253) of patients, including fatigue, pruritus, nausea, joint pain, and upper-respiratory tract infection. One patient had a suspected allergic reaction to the first infusion and treatment was not continued. In 1.9% (5/253) of patients, treatment was discontinued d/t adverse events. No serious adverse events were observed.

Conclusion: In this large real-world experience in patients with CD, we found that risankizumab has excellent efficacy and safety, with notable effectiveness in ustekinumab-experienced patients.

Disclosure: Nothing to disclose.

Introduction: Risankizumab (RZB) is an interleukin [IL]-23 p19 inhibitor approved for the treatment of Crohn’s disease (CD). In the SEQUENCE head-to-head trial in patients with moderately to severely active CD, RZB was more effective in achieving endoscopic outcomes over ustekinumab (UST; IL-12/IL-23 p40 inhibitor),¹ with higher rates of endoscopic remission, regardless of CD location, observed in post hoc analyses.²⁻³ Here, we evaluate the changes from baseline in Simple Endoscopic Score for Crohn’s Disease (SES-CD) total score and SES-CD components at weeks 24 and 48.

Aims & Methods: SEQUENCE was an open-label, multicenter, randomized, efficacy assessment-blinded study in adults with moderately to severely active CD who had experienced inadequate response to ≥ 1 anti-tumor necrosis factor (TNF) therapy. Patients in the primary efficacy analysis set were randomized 1:1 to receive RZB (intravenous [IV] 600 mg induction dose at weeks 0, 4, and 8, followed by a subcutaneous [SC] 360 mg maintenance dose every 8 weeks starting at week 12) or UST (single weight-based IV induction dose, followed by a SC 90 mg maintenance dose every 8 weeks starting at week 8) up to week 48. A mandatory corticosteroid taper started at week 2. In this post hoc analysis, the mean changes from baseline in total SES-CD score and individual SES-CD components (affected surface, ulcerated surface, size of ulcers, and presence of narrowing) at weeks 24 and 48 were evaluated. Data include patients with nonmissing values at both baseline and the corresponding visit; all P values are nominal.

Results: Of 520 enrolled patients (RZB, 255; UST, 265), evaluable endoscopy data were available at week 24 for 461 patients (RZB, 238; UST, 223) and at week 48 for 379 patients (RZB, 210; UST, 169). Baseline SES-CD scores were generally similar between treatment groups (Table). At week 24, treatment with RZB resulted in greater improvement in total SES-CD from baseline compared with UST (–6.6 vs –3.9; nominal P < .0001), and similarly, improvements at week 48 were greater with RZB vs UST (–7.3 vs –4.8; nominal P = .0006).

Further, numerically greater improvements were observed with RZB vs UST across all individual SES-CD components at weeks 24 and 48, with notable differences between RZB and UST seen in the individual SES-CD components of affected surface, ulcerated surface, and size of ulcers (nominal P < .01).

Parameter, mean (SD)	Baseline ^a		Change From Baseline at Week 24 ^a		Change From Baseline at Week 48 ^a	
	RZB (n = 238)	UST (n = 223)	RZB (n = 238)	UST (n = 223)	RZB (n = 210)	UST (n = 169)
Total SES-CD	13.4 (7.1)	13.8 (7.2)	–6.6 (7.4)***	–3.9 (6.4)	–7.3 (7.4)***	–4.8 (6.8)
SES-CD components						
Affected surface	4.7 (2.9)	5.0 (3.3)	–2.5 (2.9)***	–1.5 (3.0)	–2.6 (3.0)**	–1.8 (3.1)
Ulcerated surface	3.6 (2.4)	3.7 (2.3)	–1.9 (2.4)***	–1.2 (2.0)	–2.1 (2.4)**	–1.4 (2.2)
Size of ulcers	4.3 (2.5)	4.4 (2.5)	–2.2 (2.7)***	–1.4 (2.2)	–2.5 (2.7)***	–1.7 (2.1)
Presence of narrowing	0.8 (1.3)	0.7 (1.2)	–0.1 (1.3)	0.1 (1.1)	–0.1 (1.2)	0.1 (1.1)

RZB, risankizumab; SES-CD, Simple Endoscopic Score for Crohn’s Disease; UST, ustekinumab.
Nominal P < .01; *nominal P < .001 vs UST based on Student’s t test.
^aValues only include patients with nonmissing values at both baseline and week 24.
^bValues only include patients with nonmissing values at both baseline and week 48. Patients discontinuing the study before week 24 or 48 were not included in the analysis for that respective timepoint.

Table. Total SES-CD and Individual SES-CD Components Over Time.

Conclusion: In this head-to-head study, RZB was more effective than UST in improving endoscopic disease activity per SES-CD scores in patients with CD who had experienced inadequate response to anti-TNF therapy. Differences were observed both at weeks 24 and 48 and were driven by SES-CD components of the size of ulcers, ulcerated surface, and affected surface.

Introduction: Mirikizumab (miri), a p19-directed IL-23 antibody, has been shown to be effective in patients with moderately-to-severely active ulcerative colitis (UC) in Phase 3 trials (LUCENT-1 NCT03518086; LUCENT-2 NCT03524092).¹

The relationship between symptomatic, endoscopic, and clinical remission and levels of the inflammatory biomarker faecal calprotectin (fCAL) was studied for miri-treated patients enrolled in the trials.

Aims & Methods: This post hoc analysis evaluated patients treated with intravenous (IV) miri 300mg every 4 weeks (Q4W) until week (W)12 in induction (n=868) followed by subcutaneous miri (n=365) Q4W up to W52 (miri induction responders at W12 who were rerandomized for the maintenance period) or placebo.

The improvement in fCAL at W12 and W52 between miri and placebo were compared using Cochran Mantel Haenszel, adjusting for randomization stratification factors. Missing data were imputed as nonresponse.

The relationship between achieving symptomatic, endoscopic, or clinical remission (defined in Table) and fCAL levels at W4, W12 and W52 was assessed using receiver operating characteristic (ROC) approaches. Predictability was measured by area under the ROC curve (AUC), and AUC≤0.5 indicates no predictability. Optimal fCAL threshold was obtained based on Youden Index.

Results: Greater proportions of miri-treated patients compared to placebo achieved fCAL≤250 ug/g at W4, W12, and W52. A total of 19.0% vs. 12.5%, 34.3% vs. 20.1%, 50.7% vs 19.3% patients achieved fCAL≤250 ug/g at W4, W12, and W52 miri vs. placebo, respectively. Greater proportions of patients achieving symptomatic, endoscopic, and clinical remission reached the predefined threshold of fCAL≤250 ug/g or the optimum fCAL threshold obtained from the ROC (see Table footnote) in this study compared with those not achieving the endpoints (Table).

W4 fCAL levels had 70.5% predictability for W12 endoscopic remission and 64.9% for clinical remission, but lower predictability for symptomatic remission (59.1%). W12 fCAL levels had 83.0% predictability for W12 endoscopic remission, 78.5% for clinical remission, and 67.4% for symptomatic remission.

W52 fCAL levels had higher predictability for W52 endoscopic (76.6%) and clinical remission (72.7%) than for symptomatic remission (62.3%).

Week	Symptomatic Remission		Endoscopic Remission		Clinical Remission	
	Achieving (N=360)	Not Achieving (N=406)	Achieving (N=290)	Not Achieving (N=478)	Achieving (N=193)	Not Achieving (N=571)
Week 4						
fCAL ≤ 250 ug/g	109 (30.3)	79 (19.5) [†]	122 (42.1)	65 (13.6) [†]	77 (39.9)	110 (19.3) [†]
Optimum fCAL threshold	193 (53.6)	159 (39.2) [†]	158 (54.5)	106 (22.2) [†]	103 (53.4)	168 (29.4) [†]
Week 12						
fCAL ≤ 250 ug/g	200 (55.0)	116 (29.2) [†]	216 (73.7)	100 (21.2) [†]	151 (75.9)	164 (29.2) [†]
Optimum fCAL threshold	237 (65.1)	149 (37.4) [†]	216 (73.7)	93 (19.7) [†]	151 (75.9)	157 (27.9) [†]
Week 52						
fCAL ≤ 250 ug/g	161 (70.0)	22 (50.0) [*]	151 (80.3)	38 (40.9) [†]	133 (80.1)	49 (45.8) [†]
Optimum fCAL threshold	161 (70.0)	21 (47.7) [*]	134 (71.3)	24 (25.8) [†]	129 (77.7)	42 (39.3) [†]

Table. Faecal Calprotectin Normalization at Week 12 in LUCENT-1 and Week 52 in LUCENT-2 per achievement of efficacy outcomes.

ES=Endoscopic Subscore; fCAL=Faecal Calprotectin; RB = Rectal Bleeding; SF=Stool Frequency.

Data shown as n(%). * $p < 0.05$ and $^{\dagger}p < 0.001$ from Fisher's exact test. Symptomatic remission: SF=0 or 1 with a ≥ 1 -point decrease from baseline, RB=0. Endoscopic remission: ES=0 or 1 (excluding friability). Clinical remission: SF=0 or 1 with a ≥ 1 -point decrease from baseline, RB=0, and ES=0 or 1 (excluding friability). Optimal fCAL for symptomatic/endoscopic/clinical remission: $\leq 585/\leq 390/\leq 415$ ug/g at Week 4; $\leq 365/\leq 230/\leq 230$ ug/g at Week 12; $\leq 230/\leq 150/\leq 205$ ug/g at Week 52.

Conclusion: These results support the use of fCAL as an early predictor of clinical outcomes and as a non-invasive biomarker for predicting clinical outcomes.

Introduction: Inflammatory Bowel Diseases (IBD) are chronic inflammatory disorders of the gastrointestinal tract, characterized by a relapsing-remitting course, primarily comprising Ulcerative Colitis (UC) and Crohn's Disease (CD). These conditions, which lack a clearly defined cause, pose significant interest to the medical community for identifying reliable predictors of disease progression and treatment response.

The specific profile of extrachromosomal circular DNA fragments (eccDNA) has emerged as a promising diagnostic and prognostic biomarker for

various types of cancer. However, their role in IBD patients, including the specific gene fragments they carry, has not been thoroughly investigated so far.

Aims & Methods: This monocentric, observational, case-controlled study enrolled consecutive patients diagnosed with IBD and non-IBD healthy controls undergoing colonoscopy for colorectal cancer screening at Fondazione Policlinico Universitario “A: Gemelli”. Disease activity in IBD patients was assessed using different scoring systems: the Partial Mayo Score (PMS) and Mayo Endoscopic Subscore (MES) for UC, and the Harvey-Bradshaw Index (HBI) and Simple Endoscopic Score for CD (SES-CD) for CD. Colonic biopsies were obtained from both inflamed and healthy mucosa of IBD patients and from non-IBD controls. Purification of human eccDNA was optimized according to the Circle-Seq method, including eccDNA enrichment, removal of linear and mitochondrial DNA, rolling-circle amplification and sequencing; subsequently, eccDNAs were identified using Circle Finder software. The study compared the relative abundances of genes within eccDNAs between IBD patients and non-IBD controls, focusing on those that were differentially abundant, defined as *Differentially Produced per Gene eccDNAs (DPpGCs)*.

Results: 133 patients with IBD (69 with CD, 64 with UC) and 17 healthy controls (HC) were included in the study. Colonic mucosal samples from IBD patients revealed a higher average abundance of eccDNAs compared to samples from HC. This increase was consistent across all chromosomes, suggesting a global upregulation of eccDNA production throughout the human genome. Furthermore, there was a slight yet statistically significant trend towards larger eccDNAs sizes in IBD patients compared to HC. Even when considering only eccDNA derived from genic elements (“genic eccDNAs”), IBD patients exhibited a significantly higher abundance of eccDNA in the gut compared to non-IBD controls.

Further analysis focused on DPpGCs with a fold change $>1 \log_2$ between IBD patients and HC, with a significance threshold of $p < 0.01$. Forty-nine genes were found to be enriched in IBD patients, including GRID2 and NRG3. Similarly, in CD patients, 176 genes, such as FGF14, SOX5, and ZBTB20, were significantly enriched compared to HC. In UC patients, 31 genes, including NRG1, SPOCK3, and ATP13A4, showed enrichment compared to HC. Moreover, IBD patients in endoscopic remission (SES-CD < 3 , EMS of 0-1) tended to have fewer eccDNAs in their intestines compared to those with active disease, although this difference did not reach statistical significance. Five DPpGCs, including FARS2, HERC3, and PNK2, were identified when applying the aforementioned criteria.

Conclusion: In conclusion, our study unveils a distinct pattern of eccDNA production specific to IBD. We showed that circles harboring specific genes can distinguish UC and CD from healthy controls with statistical significance ($p < 0.01$). We suggest that eccDNA identification may serve as a novel diagnostic biomarker for IBD patients.

Introduction: Ulcerative colitis (UC) is characterized by chronically relapsing inflammation of the colonic mucosa. Tofacitinib (TOFA) is a pan-inhibitor of the JAK kinases, a family of intracellular kinases involved in the signal transduction pathway of multiple inflammatory signals. Despite the efficacy shown by TOFA in inducing and maintaining remission in moderately-to-severely active UC, rates of primary non response remains high. We propose a new method to identify predictors of responsiveness to TOFA based on “ex-vivo” challenge of organ cultures from biopsies collected from candidate patients.

Aims & Methods: Baseline biopsies from inflamed areas of UC patients with active disease and candidate to receive TOFA 10mg b.i.d. for 8 weeks, were used for “ex-vivo” organ culture and stimulated with TOFA 20 μ M and 200nM or left untreated. After 24 hours, proteomic analysis was performed and quantitative expression of 92 inflammation-related human proteins (Olink® Human Inflammation panel) was correlated with week 8 clinical response defined by Modified Mayo Score (MMS). Intestinal biopsies were also collected at baseline and at 8 weeks for proteomic analysis. To decipher the nature of TOFA's effects, both unsupervised and supervised machine learning (ML) methods were employed (sklearn module, Python). The K-means method was used for unsupervised learning followed by a supervised ML approach to classify week 8 responders and non-responders. Data were transformed in into a second-order polynomial format and logistic regression was used for modelling.

Results: Between January 2022 and January 2023, 17 UC patients were enrolled. At week 8, 13/17 (76.5%) patients treated with TOFA showed clinical response. Unsupervised ML, utilizing proteomic data from organ cultures stimulated with TOFA 200nM, achieved a 90% success rate in predicting a positive clinical response. This prediction was based on forming two distinct clusters, with significant contributions from key variables such as CASP-8, CCL19, CCL20, CD5, CXCL9, EN-RAGE, GDNF, HGF, IL-18R1, MCP-1, MCP-2, MCP-4, MMP-10, OPG, PD-L1, STAMBP, TNFRSF9, TRANCE, TWEAK, and VEGFA. In our supervised ML approach, logistic regression was employed with 30 shuffle splits to refine the predictive model. The mean precision value for the best profile, logistic regression with Ridge regularization, was 0.73. We also discovered that transforming the dataset into second-order polynomial format significantly enhanced the model's performance. In this case, the most effective logistic regression model achieved a mean precision score of 0.82.

Conclusion: Our predictive model demonstrates a high level of precision in identifying positive treatment responses, emphasizing the potential of further dataset expansion and the use of advanced machine-learning to predict response in TOFA-treated UC patients.

Introduction: Iron deficiency anaemia (IDA) is a common comorbidity in inflammatory bowel diseases (IBD). Previous studies have already showed the predictive value of anaemia on hospitalization and mortality rates, however, these studies did not focus on the effect of IDA on patients with clinical and biochemical remission, however, due to the ethiopathology, certain effects are hypothesized.

Aims & Methods: This was a multicenter retrospective real-life cohort study assessing the effect of IDA on clinically and biochemically inactive IBD patients. We included patients from the outpatient setting who has been followed-up for a year. Patients with need of blood transfusion at baseline were excluded. IDA was defined as no clinical and biochemical activity, ferritin <30 µg/mL and transferrin saturation <20% with the presence of anemia. Primary outcome was disease aggravation, defined as need of change in the current treatment/hospitalization/abdominal surgery. Secondary outcome was proportion of major complications, defined as need of hospitalization/abdominal surgery. Pearson’s chi squared sample size calculation (n=720) was performed on our pilot results based on 200 IBD patients.

Results: In total, 711 patients (median age: 43.1 years [IQR: 32.3 - 49.6]; male/female ratio: 332/379; CD: 397, UC: 311; IDA/non-IDA 85/623) were enrolled. Mean follow-up period was 1.1±0.28 years. The presence of IDA increased the risk of disease aggravation (OR: 1.7) and major complications (OR: 2.8). Furthermore, male sex (OR: 0.6) and older age (OR: 0.8) were protective, and ileocecal resection (OR: 2.0) and higher C-reactive protein levels (OR: 1.5) increased the disease aggravation.

Conclusion: IDA predicts the risk of relapse at some degree in patients with clinical and biochemical remission in the outpatient setting. IDA may help to identify underlying disease activity in patients with clinical and biochemical remission in time, therefore, we recommend to be implemented in the treat-to-target approach.

Introduction: The vedolizumab clinical decision support tool (VDZ-CDST) was developed and validated as a clinical prediction tool for vedolizumab (VDZ) use in Crohn’s disease (CD). It has demonstrated prognostic value

with the ability to stratify patients by probability of clinical and endoscopic response to VDZ at week 26. We examined the applicability of the tool in a real-world dataset of VDZ treated CD patients.

Aims & Methods: We performed a retrospective data collection and analysis at a single tertiary centre on patients who had started VDZ between January 2015 to February 2022. We collected baseline data to calculate the CDST: prior exposure to tumour necrosis factor (TNF) antagonists, prior surgery for CD, prior fistulating disease, baseline albumin and C reactive protein (CRP). Our main endpoints were treatment persistence at 12 and 24 months. We also retrieved the following parameters of disease activity at 12 month follow up: CRP, faecal calprotectin (FCP), mucosal healing (defined as ulcer free endoscopy) and progression to surgery. Chi square for trend was used for 12 month persistence and Kaplan-Meier curves with log rank test for trend was used for 24 month persistence. ANOVA was used for comparing continuous variables.

Results: 130 patients were included. 74.6% had prior TNF antagonist exposure, median baseline CRP was 4 mg/L, and median albumin was 43 g/L. Using the CDST at baseline, 3 groups were defined – 9 (7%) were low, 51 (39%) were intermediate, and 70 (54%) had a high probability of treatment response. One year treatment persistence rates were 56%, 69%, and 80% in the low, intermediate and high probability groups respectively (p=0.048). Kaplan-Meier analysis demonstrate increasing rates of persistence at 24 months in keeping with CDST-defined probability of response (p=0.035). There were also statistically significant differences in outcomes across the 3 groups, with lower CRP at 12 months, higher rates of mucosal healing and lower rates of progression to surgery in the high probability group versus the low and intermediate groups.

	Low probability group n = 9 (%)	Intermediate probability group n = 51 (%)	High probability group n = 70 (%)	p value
Treatment persistence at 12 months	5 (56)	35 (69)	56 (80)	0.048
CRP at 12 months, median (mg/L)	10	3	2	0.015
FCP at 12 months, median (µg/g)	223	209	92	0.59
Mucosal healing	1/5 (20)	13/28 (46)	28/37 (76)	0.0023
Surgery for CD	3 (33)	16 (31)	11 (16)	0.042

Conclusion: The prognostic value of the VDZ-CDST appears valid in a real-world CD cohort with high rates of prior TNF antagonist exposure. The tool has demonstrated predictive ability for long-term treatment persistence as well as measures of biochemical and endoscopic activity. Our study is consistent with a growing body of published evidence on the applicability of CDST and suggests a role for CDST in guiding therapeutic decision making in routine clinical practice.

Introduction: Crohn's disease (CD) is a chronic inflammatory disease of the gastrointestinal tract. Current therapies include monoclonal antibodies, such as adalimumab (ADA) and infliximab (IFX), that target the inflammatory cytokine tumor necrosis factor alpha, collectively known as anti-TNF. While it has been shown that anti-TNF is effective at inducing and maintaining remission in patients with CD, this treatment fails in up to 40% of CD patients. Ineffective treatment results in disease progression and complications, emphasizing the need to understand mechanisms behind non-response and to define prognostic biomarkers. We previously identified differences in the peripheral blood DNA methylome associated with response and non-response. However, it is unclear how differential methylation can affect the transcriptome.

Aims & Methods: In this study, we assembled a cohort of 58 adult CD patients that were scheduled to start ADA or IFX treatment. Response to treatment was assessed after 6-9 months based on strict combination of endoscopic ($\geq 50\%$ reduction SES-CD), biochemical (CRP reduction $\geq 50\%$ or CRP ≤ 5 mg/L and FCP reduction $\geq 50\%$ or FCP ≤ 250 $\mu\text{g/g}$) and clinical criteria (≥ 3 point drop in HBI or HBI ≤ 4 without corticosteroids). Whole peripheral blood leukocytes (PBL) were collected from patients before baseline endoscopy or at first infusion/injection, and 6-9 months later. mRNA was extracted using QIAasympyphony system, converted into cDNA and sequenced in a paired-end format on the Illumina NovaSeq at the Amsterdam UMC Core Facility Genomics. Differential expression (DE) analysis was carried out within the R statistical environment (v 4.3.1) using the Bioconductor package DESeq2 (v 1.40.2).

Results: Prior to the start of treatment, we identified 504 and 750 differentially expressed genes (DEGs) distinguishing responders from non-responders in ADA and IFX cohorts, respectively. While 13 genes presented response-associated differential expression for both ADA and IFX, no overall correlation was observed between response-associated differential expression profiles. However, based on canonical pathway analysis, we found that expression differed in both ADA and IFX responders and non-responders at the level of neutrophil degranulation, B-cell receptor regulation, and cell growth and differentiation.

Conclusion: Our data suggest that response to ADA and IFX can be associated to the PBL transcriptome prior to treatment. Furthermore, while the differences between responders and non-responders to ADA and IFX display limited overlap in DEGs, we observe that response-associated pathways are shared.

Disclosure: Nothing to disclose.

Introduction: Patients with ileocolonic Crohn's disease are often treated with biologics. However, many patients develop complications and need surgery. Ileocolonic resection (ICR) is associated with a very high risk of postoperative recurrence.

Aims & Methods: The aim of this study was to identify predictors of early postoperative endoscopic recurrence. This is a prospective multicentre international study. All patients who had ICR for CD were eligible. Demographic and clinical data, as well as past-medical history, including prior exposure to immunosuppressant and biologics (anti-TNFs, ustekinumab, vedolizumab, others), number of lines of biologics used before surgery, were recorded. A prophylactic treatment was discussed according to a pre-established algorithm, based on the following risk factors: current smoking, previous ICR, penetrating phenotype and active perianal disease. Endoscopic recurrence was defined as a Rutgeerts score $\geq 2b$. The identification of factors associated with the endoscopic recurrence was performed by logistic regression model.

Results: 874 patients have been included between 2010 and December 2023 patients; 625 CD patients who had a colonoscopy performed within the year after surgery were included in the analysis. The median [IQR] age at surgery was 34 years [26.00, 45.00], 308 (49.3%) patients were male. Median disease duration was 7.70 years [2.90, 14.10].

At time of surgery, 202 patients (32.3%) were active smokers and 167 (26.7%) were ex-smokers. Three quarters of the patients (n=461, 74%) had been exposed to at least one biologic therapy before surgery. In most cases, only one anti-TNF agent was used before surgery (n=334); 136 patients (21%) received two biologics or more.

Half of the patients (n=311) received a prophylaxis after surgery, with thiopurines alone (n=68) or a biologic therapy [n=254: Anti-TNF (n= 158), ustekinumab (n=76), vedolizumab (n=20)]. The median time between

surgery and colonoscopy was 6.40 months [6.00, 7.40]. Endoscopic recurrence (modified Rutgeerts score ≥ 2), occurred in 235 patients (37.6%). In multivariate analysis, active smoking [OR 2.74 (95%CI: 1.73, 4.37), $p < 0.001$], exposure to biologics before surgery [OR 2.66 (95%CI: 1.51, 4.78), $p < 0.001$], prior ICR [OR 1.69 (95%CI: 1.03, 2.77) $p = 0.038$], male gender [OR 1.79 (95%CI: 1.2, 2.63), $p = 0.004$], and a temporary stoma [OR 2.97 (95%CI: 1.40, 6.59), $p = 0.004$] were associated with an increased risk of postoperative endoscopic recurrence; while prophylaxis by biologics was protective [OR 0.44 (95%CI: 0.25, 0.78), $p < 0.001$].

Conclusion: In this large multicentre prospective study of CD patients included at time of an ileocolonic resection, we show that smoking and prior exposure to biologics are the strongest predictors of early postoperative recurrence. To our knowledge, this is the first study demonstrating the impact of prior exposure to biologics on the risk of postoperative recurrence in CD.

UNMASKING CROHN’S DISEASE: NOVEL ANTI-GLYCAN ANTIBODIES MAY IMPROVE DIAGNOSTIC ACCURACY WHILE PROVIDING PROGNOSTIC VALUE, ESPECIALLY IN ASCA-SERONEGATIVE PATIENTS

J. Yang¹, A. Aikins², D. Alfego², K.Y. Chun¹
¹Labcorp, Specialty Medicine, Calabasas, United States of America, ²Labcorp, Center for Excellence in Data Science, Artificial Intelligence and Bioinformatics, Burlington, United States of America

Contact E-Mail Address: yangj5@labcorp.com

Introduction: Anti-Glycan Antibodies (AGA), gASCA (Anti-*Saccharomyces cerevisiae*) together with the more novel ACCA (Anti-chitobioside), ALCA (Anti-laminaribioside), and AMCA (Anti-mannobioside) are antibodies specific to Crohn’s Disease (CD) that target glycans (polysaccharides) found in microorganisms, such as *C. albicans* and *S. cerevisiae* and may alter the immune response to fungal dysbiosis. The presence of AGA in patient serum differentiates CD from ulcerative colitis (UC) and non-IBD with about 85% specificity. Moreover, concomitant positivity of 2 or more AGA increases CD specificity (>95%) and predicts faster progression to more severe disease with strictures and fistulae.

This diagnostic accuracy of AGA has been validated by more than a dozen independent, peer-reviewed studies in over 4000 IBD patients.¹ More recent utilization and real-life performance of AGA in clinical practice have yet to be characterized.

Aims & Methods: We assessed the utilization and positivity of 4 AGA in 163,364 patient samples when ordered as the IBD Expanded Profile from January 2012 through March 2024. The antibodies, gASCA, ACCA, ALCA and AMCA, are detected in serum, quantitated by enzyme-linked immunosorbent assays (ELISA) using phophomannan, chitobioside, laminaribioside, and mannobioside, and reported in units where >50, >90, >60, and >100, respectively, are positive. gASCA utilizes an improved purified form of mannan and is comparable to conventional ASCA.

Results: Of a total of 163,394 patient samples, one quarter (25.2%) were positive for at least one AGA. Isolated positivity of only one AGA was found in 18.3% where gASCA alone was the most common (7.0%) followed by AMCA (6.1%).

Concomitant positivity of 2 or more AGA occurred in only 7.0% of all samples with the most frequent co-occurrences, ALCA + AMCA and AMCA + gASCA. Individual AGA frequencies were gASCA (11.3%), AMCA (11.3%), ALCA (7.2%), and ACCA (4.3%). Median antibody levels (interquartile range) for positive samples were: gASCA 66.0 (57.0-84.0), ACCA 124.0 (104.0-167.0), ALCA 76.0 (67.0-92.0) and AMCA 147.0 (118.0-205.0).

Isolated Positivity of 1 AGA	n (% of total)	Concomitant Positivity of 2 AGA	n (% of total)	Concomitant Positivity of 3 or 4 AGA	n (% of total)
ACCA only	3623 (2.2%)	ALCA + gASCA only	1,567 (1.0%)	ALCA + gASCA + AMCA only	1,257 (0.8%)
ALCA only	4832 (3.0%)	ALCA + AMCA only	2,609 (1.6%)	ALCA + gASCA + ACCA only	185 (0.1%)
AMCA only	9888 (6.1%)	ACCA + ALCA only	300 (0.2%)	ALCA + AMCA + ACCA only	546 (0.3%)
gASCA only	11,508 (7.0%)	AMCA + gASCA only	2,466 (1.5%)	gASCA + AMCA + ACCA only	370 (0.2%)
		ACCA + gASCA only	743 (0.5%)	gASCA + AMCA + ACCA + ALCA	437 (0.3%)
		ACCA + AMCA only	891 (0.5%)		

Table 1. Anti-Glycan Antibodies in 163,394 Patient Serum Samples.

Conclusion: Serum AGA were frequently positive in over 160,000 patient samples. One quarter (25.2%) of all samples were positive for at least one AGA supporting their potential usefulness in differentiating CD from UC and non-IBD. Most positivity (18.3%) occurred as one isolated positive AGA (~85% specific for CD). A smaller subset, 7.0%, had 2 or more AGA and as such, are associated with a very high specificity (>95%) for CD as well as an odds ratio of 3 for severe disease and need for abdominal surgery.^{1,2} Of note, most samples (88.7%) were seronegative for gASCA, reiterating the limited sensitivity of conventional IBD serology (only pANCA and ASCA). Of 144,864 gASCA-seronegative samples, a substantial number, 18,533 (13.9%), were positive for one or more of the novel AGA (ACCA, ALCA or AMCA). This result substantiates the potential incremental benefit of these novel Anti-Glycan Antibodies in identifying those patients more likely to have CD and its disease complications.

RED CELL DISTRIBUTION WIDTH (RDW) TO PLATELET RATIO (RPR): A ROUTINELY PERFORMABLE TOOL TO PREDICT 7-YEAR RISK AND MODALITIES OF DECOMPENSATION IN ADVANCED CHRONIC LIVER DISEASE (ACLD). A PRELIMINARY OBSERVATION

Introduction: The decompensation occurrence constitutes the main factor affecting survival for compensated advanced chronic liver disease (cACLD) patients. Based on the type of first decompensation event (DE), two distinct modalities of progression, with relatively different prognostic implications, have been described: "Non-Acute" (NAD) [slow ascites onset, mild hepatic encephalopathy (HE), or progressive jaundice] or "Acute" (AD) [grade 2/3 ascites within 2 weeks, severe HE, or acute bleeding]. Clinically significant portal hypertension (CSPH), defined by Hepatic Venous Pressure Gradient (HVPG) values ≥ 10 mmHg, represents the best predictor for decompensation. However, it's affected by the invasiveness, the general availability, and the relative strict operator dependence. Alternatively, various noninvasive tools (NITs), usually adopted to estimate liver function and hepatic fibrosis, have been proposed to predict decompensation.

Red cell distribution width (RDW)/Platelet ratio (RPR) has recently been suggested as a routinely assessable NIT predicting fibrosis severity in chronic hepatopathies. However, its predictive role in ACLD patients has never been explored.

Aims & Methods: We aimed to evaluate the accuracy of the RPR in predicting the occurrence and modalities (NAD or AD) of the first DE in cACLD patients.

In this observational study, 140 controls and 680 cACLD patients of various etiologies were prospectively enrolled and followed up (FU) semiannually for 7 years. At baseline, biochemical, clinical, and Liver Stiffness Measurement (LSM) data were collected, as well as the Child-Pugh (CP), MELD, AST/Platelet Ratio Index (APRI), Fibrosis-4 score (FIB-4), Albumin-Bilirubin (ALBI), ALBI-FIB-4, and RPR were calculated. CSPH was defined by the presence of endoscopic esophageal varices and/or assumed for LSM values > 25 kPa. During FU the DEs were recorded.

Results: 208 (30.5%) cACLD patients progressed to decompensated ACLD (dACLD): 141 (67.8%) presented NAD and 67 AD (32.2%) as first DE. Baseline RPR resulted significantly higher in dACLD patients compared to cACLD and controls, as well as in AD patients compared to NAD (all $p < 0.0001$). RPR positively correlated with APRI, FIB-4, ALBI, ALBI-FIB-4, MELD, CP, and LSM [R:0.88, R:0.81, R:0.61, R:0.74, R:0.68, R:0.75, R:0.74, R:0.94; all $p < 0.0001$]. ROC analysis revealed RPR ≥ 0.472 and ≥ 0.894 as the best cut-offs [AUC: 0.95; AUC: 0.94] in the prediction respectively of 7-year first DE and relative modality (AD), as well as better predictive performance if compared to APRI [AUC:0.87; AUC:0.90], FIB-4 [AUC: 0.71; AUC:0.80], ALBI [AUC:0.90; AUC:0.77], ALBI-FIB-4 [AUC: 0.93; AUC:0.79], MELD [AUC:0.78; AUC:0.89], CP [AUC:0.77; AUC:0.71], and LSM [AUC:0.87; AUC:0.94] for both first DE and AD occurrence (all $p < 0.0001$). Multivariable analysis revealed the RPR [adjusted hazard ratio (aHR): 2.24[MD1] [MR2]] and the presence of baseline CSPH (aHR:1.84) as the variables independently and significantly influencing both outcomes (all $p < 0.0001$). The Kaplan-Meier Log-Rank Test analysis on DE occurrence showed HR:4.62 [C.I. 95% 3.110-5.810] for baseline RPR ≥ 0.472 and HR: 5.10 [C.I. 95% 3.481-6.125] for patients presenting simultaneously baseline RPR ≥ 0.472 and CSPH.

Conclusion: The availability of a non-invasive tool predicting the decompensation is an unmet need. RPR non-invasively predicts the timing and modalities of decompensation in cACLD patients representing a potential clinically useful biomarker in this context.

NATURAL HISTORY AND RENAL INVOLVEMENT OF CONGENITAL HEPATIC FIBROSIS AND CAROLI DISEASE - A SINGLE CENTER EXPERIENCE

D. Janakiraman¹, N. Dheivamani¹, S. T A¹, S.K. R¹, W. Thomas¹
¹Institute Of Child Health/Madras Medical College, Paediatric Gastroenterology, Chennai, India

Contact E-Mail Address: rdherdhe9@gmail.com

Introduction: Congenital hepatic fibrosis (CHF) is a rare autosomal recessive disease derived from biliary dysgenesis secondary to ductal plate malformation; it often coexists with Caroli's disease, von Meyenburg complexes, autosomal dominant polycystic kidney disease (ADPKD), and autosomal recessive polycystic kidney disease (ARPKD). Congenital hepatic fibrosis (CHF) and Caroli syndrome has varied clinical presentations with or without renal involvement.

Aims & Methods: Our study aimed to describe the clinical manifestations and natural history of children with CHF and Caroli with or without renal involvement. Retrospective data from January 2022 to January 2024 was collected and analyzed.

Results: Twenty-three children (Caroli=7, CHF=16) were enrolled male predominance (76%) was noted. Consanguinity was noted in 76% and 23% had affected siblings. Median age at initial presentation was two years and abdominal distension was the most common presentation (47.6%) followed by variceal bleeding (23.8%), cholangitis (14.2%), incidental diagnosis (9.5%) and pancytopenia (4.76%). Median age at presentation and diagnosis was later with variceal bleeding at 5.6 years compared with children with abdominal distension who presented at 18 months respectively ($p=0.0001$). Renal involvement was present in 76% of the children. Autosomal Recessive Polycystic Kidney Disease (ARPKD) was the most common renal manifestation noted. Of them, 18% had developed Chronic Kidney Disease (CKD). All Caroli cases (100%) had renal involvement. There was no statistical difference in the age of presentation of CHF with or without renal involvement ($p=0.5998$). Growth faltering was noted in 52% of children. Statistical analysis revealed no significant difference in the likelihood of developing portal hypertension among children with either congenital hepatic fibrosis (CHF) or Caroli disease, regardless of renal involvement. Portal hypertension was seen in 76%. Only one child had variceal bleeding on follow up.

Conclusion: Abdominal distension, organomegaly, variceal bleeding, and cholangitis are frequently observed clinical manifestations in both congenital hepatic fibrosis (CHF) and Caroli disease. Interestingly, while renal involvement is more prevalent in Caroli disease compared to CHF, there

doesn't appear to be a direct correlation between renal involvement and the severity of hepatic manifestations or growth faltering in affected children. This underscores the complexity of these conditions and the need for tailored management approaches that address both hepatic and renal complications.

Introduction: Since 2010 (1), little data has been available in France on the management of severe acute alcoholic hepatitis (SAH). In order to obtain a current "mapping" of the management of severe HAS in France, a practice survey was conducted from 04/2022 to 07/2023.

Aims & Methods: A Google questionnaire pre-established by a working group was sent to all the hepatogastroenterology departments of general hospitals (nUH), the hepatology departments of university hospitals (UH). The results are expressed as means $\pm$ SD. Data analysed: demographics, type of practice (university hospital, general hospital), predominant speciality, experience, number of AA treated per centre with corticosteroids (C) or N-acetylcysteine corticosteroids (NAC). Existence of an AA treatment

protocol. Systematic use of transjugular liver biopsy (LB), on-site LB, time taken to obtain results. Treatment: use of C alone or C-NAC. Screening for bacterial infections, use of antibiotic therapy (ATB) in the event of infection, time taken to start treatment for AA. Whether or not to use C in antigen-positive HBs patients (with or without pre-emptive treatment). Interruption of C in the event of an intermediate Lille score at D7. Indication for transfer to a liver transplant centre.

Results: 465 respondents (R): 40 years (12.5); 50% M, 50% F, UH 53.3%, nUH 46.7%, hepatologists 57%, gastroenterologists 39%, juniors 21%. Number of AA treated with CS or CS NAC 25 (0 to 300); the number of AA treated in UH was higher than in non UH: 34 (29), nUH 15.4 (13.4), $p < 0.001$. Treatment protocol for AA, 62% (University Hospital) vs 42% (Hospital), $p < 0.001$. LB systematically performed: 98% AA vs 50% other, $p < 0.001$. Time taken to obtain LB (days): 3.4 (UH) vs 4.9 (nUH), $p < 0.001$. Nutritional status was assessed by 98% of patients. A systematic chest CT scan was routinely requested by 34% of patients in the event of suspected pulmonary infection (UH versus nUH ns); 83% of patients waited 4 days (2-6) before starting treatment in the event of documented infection. Treatment: C alone 70% of patients (UH vs nUH ns), NAC use: UH 40% vs nUH 47.3% (ns). Treatment protocol for alcohol withdrawal syndrome: 86.3% nUH vs 76.3% UH ($p < 0.01$). CS stopped in the event of an intermediate Lille score at D7: 80% nUH vs 77% UH; ns. 69% of R's were responsible for initiating treatment. 68.2% of R were responsible for initiating treatment; 64.7% in UH vs 72.3% (NS); 80.6% senior doctors vs 20.4% junior doctors ($p < 0.001$). 62% of R used pre-emptive treatment before CS in the case of a positive HBs antigen; 59.4% in UH vs 65% in nUH ($p = 0.004$) and 76% used upper gastrointestinal endoscopy if there had been none previously, 77% in UH vs 75% nUH ($p = 0.782$).

Conclusion: The results of this study of national practice carried out in a large sample of doctors practising in or outside university hospitals show a disparity in the use of LB in cases of suspected severe AA, since 50% of R outside university hospitals do not use LB, mainly because of the absence of local possibilities. Dual C-NAC therapy is used fairly frequently. There is a disparity between university hospitals and general hospitals in the management of alcohol withdrawal syndrome and pre-emptive treatment in cases of positive HBs antigen. This study provides an update on the management of severe AA in France.

CLINICAL FEATURES AND TREATMENT OUTCOMES OF HEPATOBILIARY TUBERCULOSIS: A CASE SERIES AND LITERATURE REVIEW

T.P. Madrigal¹, C.J. David², A.M. Valle³, M.T. Panlilio¹

¹University of the Philippines - Philippine General Hospital, Division of Gastroenterology, Manila, Philippines, ²University of the Philippines - Philippine General Hospital, Department of Radiology, Manila, Philippines, ³University of the Philippines - Philippine General Hospital, Department of Laboratories, Manila, Philippines

Contact E-Mail Address: madrigalt21@gmail.com

Introduction: Hepatobiliary tuberculosis (HBTB) is an uncommon manifestation of *Mycobacterium tuberculosis* infection. It can present as an isolated involvement of the liver, bile duct, gallbladder, or, more commonly, as part of a disseminated process. HBTB poses a diagnostic challenge due to its varied clinical manifestations and potential for mimicking other hepatic disorders, particularly malignancies. Despite advancements in diagnostic techniques, no finding is considered pathognomonic, making the definitive diagnosis of HBTB reliant on histologic or microbiologic confirmation.

Aims & Methods: The records of patients with bacteriologically confirmed or biopsy-proven HBTB were reviewed for the following data: demographic features, clinical manifestations, laboratory and imaging results, and clinical follow-up. The histologic findings of granulomatous inflammation and Langhan's type giant cells, identification of acid-fast bacilli, or a positive PCR test result were used to diagnose HBTB.

Age/ Sex	Site/s of Involvement	Other Organ Involvement	History of Prior PTB Treatment	Duration from onset of symptoms to presentation	Imaging Findings	Diagnosis of HBTB	Treatment Outcome
32/M	Liver	Lungs	Yes	2 months	Multiple, hypodense nodular densities with internal calcifications	Biopsy of liver nodule Sputum MTB PCR	Improved
36/F	Gallbladder Bile ducts	CNS Lymph nodes	None	8 months	Gallbladder hydrops Intrahepatic and extrahepatic bile duct ectasia secondary to stricture formation. Retropertitoneal lymphadenopathies	Biopsy of brain mass Bile TB PCR	Improved
39/M	Bile ducts Liver	Lungs Lymph nodes	None	2 months	Multiple, hypodense nodular densities with internal calcifications and hepatic abscess Intrahepatic and extrahepatic bile duct ectasia secondary to stricture formation.	Hepatic abscess AFB staining Sputum AFB staining	Improved
31/F	Liver	Duodenum Lymph nodes Lungs	None	5 months	Intra-abdominal and retroperitoneal lymphadenopathies Multiple, hypodense nodular densities with internal calcifications	Biopsy of liver nodule	Improved
39/M	Liver Bile ducts	Lungs Lymph nodes	Yes	3 months	Intra-abdominal lymphadenopathies Intrahepatic and extrahepatic bile duct ectasia secondary to stricture formation. Hepatic mass with associated capsular retraction	Biopsy of liver mass	Developed liver cirrhosis
39/M	Liver Bile Ducts	Lungs	None	12 months	Intra-abdominal lymphadenopathies Intrahepatic bile duct ectasia secondary to stricture formation. Hepatic mass with internal calcifications	Biopsy of liver mass Bile AFB staining	Developed liver cirrhosis
50/M	Liver Bile Ducts	Lungs Lymph nodes	None	3 months	Hepatic mass with internal calcifications Intrahepatic and extrahepatic bile duct ectasia secondary to stricture formation. Intra-abdominal lymphadenopathies	Biopsy of liver mass Bile AFB staining	Mortality
51/F	Liver	Lungs Lymph nodes	Yes	3 months	Intrahepatic bile duct ectasia secondary to stricture formation. Multiple, hypodense nodular densities with internal calcifications	Biopsy of liver mass	Mortality

Results: Eight patients were included; most were male (n = 5), with a mean age of 39.6 years. Three patients had a prior history of treatment for pulmonary TB. Among them, the most common site of hepatobiliary involvement was the liver (n=7), followed by bile ducts (n = 4) and gallbladder (n=1). All patients exhibited extrahepatic involvement, primarily pulmonary (n=7). Three patients had a prior history of treatment for

pulmonary TB. The average duration from the onset of symptoms to the initial presentation was 4.8 months. The most common symptoms were abdominal pain and jaundice, followed by weight loss, fever, and anorexia. Most patients presented with a cholestatic pattern of elevation of liver function tests. Other findings include hypoalbuminemia, anemia, and leukocytosis. The most common imaging findings were the presence of lymphadenopathies, followed by intrahepatic biliary dilation, extrahepatic biliary dilation, and hepatic nodules with internal calcifications. All patients were started on anti-tubercular therapy (ATT). Four patients improved with ATT. Two patients developed secondary biliary cirrhosis despite completing ATT. Two patients succumbed to complications, one due to pulmonary embolism and the other to bacterial peritonitis.

Conclusion: The cases presented shed light on the complexities of diagnosing HBTB, emphasizing the importance of histologic or microbiologic testing to ascertain a definitive diagnosis. The importance of a multidisciplinary approach cannot be underscored in these cases. As delineated in this series, HBTB usually presents with non-specific clinical features and often exhibits extra-hepatic involvement, more commonly in the lungs. Although the majority of patients demonstrated a favorable response to ATT, patients can develop complications such as secondary biliary cirrhosis and even fatal outcomes, highlighting the importance of a high index of suspicion, particularly in endemic regions, in avoiding treatment delays and potential complications. Further studies are warranted to better understand the clinical spectrum and optimal management strategies for this uncommon yet significant manifestation of tuberculosis.

Introduction: Patients with decompensated cirrhosis have high mortality rates. Several prognostic scores have been developed, based on clinical and laboratory parameters, to assess the prognosis of patients with cirrhosis. However, to date, there is no consensus on the best prognostic model. The MELD 3.0 score was recently published with the aim of refining the MELD score to contemporary data.

Aims & Methods: The objective of this study was to evaluate and compare models based on the hepatic severity index to investigate their predictive performance in mortality.

A retrospective cohort study was conducted, including consecutively admitted patients to a Gastroenterology Department for first admission due to decompensated cirrhosis. MELD, MELD-Na, MELD 3.0, and Child-Pugh scores were calculated upon admission. Mortality at 6 weeks and 180 days was the main outcome studied.

Results: 109 patients admitted for the first episode of decompensated cirrhosis were included, 82.6% with alcoholic aetiology. Mean age was 61.8 ±10.8 years, 73.4% were men and 26.6% were women. Of the included patients, 11% died within the first 6 weeks and 25.7% died within the first 180 days after admission.

All models showed good accuracy in predicting mortality at 6 weeks and 180 days, with slight superiority of the MELD 3.0 score (AUC 0.693, 95% CI 0.598-0.778 at 6 weeks; AUC 0.712, 95% CI 0.617-0.795 at 180 days), although statistically significant differences between the different prognostic models were not observed.

Conclusion: The use of models based on hepatic severity indices accurately predicts the risk of mortality at 6 weeks and 180 days in patients with decompensated cirrhosis. The new MELD 3.0 score showed superior predictive performance in mortality, although without statistically significant differences.

Introduction: To achieve the WHO's goal of eliminating hepatitis C by 2030, higher rates of detection of people infected with the hepatitis C virus (HCV) and of treatment uptake are needed. The ELIMINATE (ELIMINATION of HCV in Austria East) project is an Austrian HCV macroelimination program that utilized readily available hospital laboratory data to identify patients with a "last positive" HCV RNA PCR, who are thus potentially still viremic, to contact them and to allow re-linkage to medical care.

Aims & Methods: Ten major liver centers in Eastern Austria participated. A systemic readout of HCV RNA PCR tests obtained between 2008 and 2020 from the respective hospital's database was conducted and between 2020 and 2023 identified people living with HCV were contacted by phone and, if unsuccessful, by letter. Patients were informed of the possibility of effective treatment via direct-acting antivirals (DAAs) and were offered a pre-treatment evaluation at the respective center.

Results: Overall, 5,695 individuals with “last positive” HCV RNA were identified (62.5% male, mean age 57.3±17.3 years). At the time of data acquisition, 1,931 (34%) had already died (33.8% liver-related deaths) and 759 (13%) had no valid contact information. At the time of recall, 1,171 (40.0%) of the 3,005 remaining patients had already achieved sustained virologic response (SVR). We successfully contacted 617 (20.5%) eligible patients, of whom 417 (67.6%) attended a pre-treatment evaluation visit. DAA therapy was started in 397 (64.3%) patients (median time from “last positive” PCR to initiation of DAA treatment: 59.8 months). As of now, SVR was confirmed in 258 patients (SVR rate 65.0%).

Conclusion: Through the ELIMINATE project we were able to identify 5,695 potentially still viremic individuals. Invalid contact information was a barrier to re-linkage to care and the amount of already diseased patients underlined the severity of the disease and the impact of potentially associated comorbidities. A systematic readout of hospitals’ HCV PCR records represents an effective macroelimination strategy to identify patients regardless of risk behavior.

Contact E-Mail Address: gabriele.rancatore@gmail.com

Introduction: Despite the introduction into clinical practice of serological neoplastic biomarkers and typical radiological characteristics, useful for the differential diagnosis of focal liver lesions, liver biopsy (LB) is still often necessary, especially in unclear cases, to achieve histological diagnosis. Nowadays, LB via percutaneous approach (PC-LB), under computed tomography (CT) scan or ultrasonography (US) guidance, is the route of choice. However, there are focal liver lesions that are poorly reachable via percutaneous approach. In these cases endoscopic ultrasound (EUS) guided fine needle biopsy (FNB) may represent an attractive minimally invasive alternative.

Aims & Methods: Aim of this retrospective observational study was to evaluate the efficacy, diagnostic performances and safety of EUS-FNB of focal liver lesions. The indication to perform EUS-LB was the presence of a focal liver lesion poorly accessible via a percutaneous approach or incidentally found during an EUS examination

Results: 58 patients were included, 43 patients had a final diagnosis of malignancy. The localization of lesions was 72.4 % (42 cases) in the left lobe and 27.6 % (16 cases) in the right lobe. The focal liver lesions localizations were summarized in Table 2. The median number of needle passes was 2 (IQR: 3–4). Only in 3 cases (5 %) the specimen was suboptimal for histological evaluation and in all of these, the focal liver lesions were located in right lobe. The overall sensitivity and specificity were 95% and 100% respectively while overall adequacy and accuracy were 95 % and 96% respectively. Subgroup analysis, conducted for different gauge FNB needles used, showed different diagnostic yield. In particular, adequacy and accuracy for 19-gauge FNB needle were 100% and 95%, adequacy and accuracy were both 100 % for 20-gauge FNB needle and were 90% and 96% for 22-gauge FNB needle. Of note, all three inadequate biopsies were performed with a 22-gauge needle. On the other hand, subgroup analysis for different FNB needle type used, showed adequacy and accuracy of 94 % and 95% respectively for Acquire needle (Boston Scientific, Natick, MA, United States) and, adequacy and accuracy of both 100% for ProCore needle (Cook Medical Inc., Winston-Salem, North Carolina, United States). Technical success was 100% both for right and left liver lobe. Adequacy for focal liver lesion located in left and right lobe was 100 % and 81.2 % respectively and the difference was statistically significant [p= 0.001]. We also compared the diagnostic yield of EUS-LB between the right lobe and left lobe mass. Median size of lesions on EUS and median number of needle passes did not differ significantly between the left and right lobes. Sensitivity for lesions located in left liver lobe and right liver lobe were 96 % and 91% respectively [p=0.001]. Specificity was 100% for lesions located in left and right liver lobe. Predictive positive value (PPV) was 100% for lesions located in both liver lobe. Predictive negative value (PPV) for lesions located in left liver lobe and right liver lobe were 90% and 50% respectively [p= 0.001]. No intra/postprocedural adverse events were recorded according to AGREE classification.

Conclusion: EUS-guided focal liver lesions biopsy using FNB is effective in achieving accurate diagnosis with an excellent safety profile. The main indication for EUS-FNB of focal liver lesions could be to obtain a specimen from the lesions located in the left liver lobe, close to big vessels or in obese patients which are more difficult to obtain by other techniques.

Introduction: Diagnosis of early chronic pancreatitis (CP) is challenging due to the limited accuracy of the available diagnostic methods. Endoscopic ultrasound (EUS) is the most sensitive method in this setting, but the specificity of mild EUS findings of CP is limited. No factor has been described to predict the progression of mild EUS changes to definite CP.
Aims & Methods: Aim of our study was to evaluate the long-term morphological and functional behavior of mild EUS changes of CP and factors associated with progression to definite CP.
Methods: A prospective longitudinal cohort study was designed. Patients with suspected early CP based on the presence of epigastric pain, toxic habits (alcohol and/or smoking) and mild changes of CP on initial EUS (3 or 4 minor criteria) with a minimum clinical and EUS follow-up of 5 years were included. Morphological progression was defined as the development of suggestive or definite EUS criteria of CP (≥5 criteria) during follow-up. Faecal elastase (FE-1) and HbA1C were measured annually for exocrine and endocrine function, respectively. Data are presented as percentages, mean±SD and OR (95%CI) and analysed by chi-squared test and logistic regression.
Results: 136 patients were included (mean age 56.5±13.3 years, 64.7% male). EUS changes progressed in 84 patients (61.8%) (group A) over a median follow-up of 8.7 years (range 5.1-14.8 years), whereas the remaining 52 patients (group B) (38.2%) did not progress. Age, sex and BMI were similar between the two groups (p=0.716). The association between toxic habits during follow-up and progression of EUS findings in the multivariate analysis is shown in the table.

Toxic habits during follow-up	Risk (OR) of morphological progression	Risk (OR) of exocrine pancreatic dysfunction
Smoking, No Alcohol	86.36 (16.74-445.50) p<0.001	5.33 (1.67-17.03) p=0.005
Alcohol, No Smoking	10.59 (3.49-32.14) p<0.001	3.12 (0.91-10.74) p=0.071
Smoking and Alcohol	150.43 (17.49-1293.97) p<0.001	5.31 (1.60-17.60) p=0.006

Smoking cessation (OR 0.24, 0.07-0.86, p=0.028) and alcohol cessation (OR 0.21, 0.06-0.82, p=0.024) were associated with lack of morphological progression of EUS changes in CP. Smoking, but not alcohol consumption during follow-up, was associated with persistent abdominal pain (OR 5.30, 2.02-13.9, p=0.001). FE-1 was normal at baseline in all patients. Impaired pancreatic secretion (FE-1 <200µg/g) was present at the end of follow-up in 32 patients in group A (38.1%) and 5 (9.6%) in group B (p<0.001). Six patients in group A required enzyme replacement therapy. The percentage of patients with diabetes at baseline (10.7% and 5.8%) and at the end of follow-up (17.9% and 9.8%) was similar in groups A and B (ns). Four patients in group A required insulin therapy.

Ongoing smoking, either as a single toxic habit or in combination with alcohol consumption, was associated with impairment of exocrine pancreatic function during follow-up (Table).
Conclusion: In patients with suspected early CP based on symptoms, toxic habits and the presence of mild EUS changes of CP, continued smoking and alcohol consumption are associated with morphological progression to definite CP and a higher risk of impaired exocrine pancreatic secretion, whereas cessation of toxic habits is protective against progression. Smoking during follow-up is associated with persistent epigastric pain.

SIRTUIN 3 ALLEVIATES THE PROGRESSION OF CHRONIC PANCREATITIS BY DEACETYLATING PYRUVATE DEHYDROGENASE COMPLEX IN PANCREATIC STELLATE CELLS

W. Li¹, J. Li¹, D. Zhang¹, Z. Jin¹, H. Huang¹
¹Changhai Hospital, Department of Gastroenterology, Shanghai, China

Contact E-Mail Address: 2239568754@qq.com
Introduction: Chronic pancreatitis (CP) is a progressive inflammatory disease of the pancreas, characterized by persistent pain and irreversible fibrosis, leading to significant morbidity[1]. The disease's progression is closely linked with the activation of pancreatic stellate cells (PSC), which are instrumental in the fibrotic remodeling of the pancreatic architecture[2]. Acetylation, a key post-translational modification, plays a crucial role in regulating cellular functions and fibrosis[3]. Sirtuin 3 (SIRT3), a mitochondrial deacetylase, plays a key role in a variety of metabolic and inflammatory diseases[4]. Preliminary evidence suggests that SIRT3 might counteract fibrosis by modulating the acetylation status of key metabolic enzymes. Among these, the pyruvate dehydrogenase (PDH) emerges as a critical target[5]. However, whether the conditioning of SIRT3 on PDH plays a role in CP progression remains unknown.
Aims & Methods: In our study, we confirmed that SIRT3 may play a key role in the course of chronic pancreatitis through immunohistochemical staining and Western Blot experiments. Subsequently, acetylation sequencing was performed on the pancreatic tissue of CP mice with normal C57 and SIRT3 knockout to target the specific action of SIRT3. We aimed to elucidate the elevated degree of acetylation and the loss of SIRT3 during CP, and to explore the potential role of the SIRT3, acetylation, and pyruvate dehydrogenase complex in the development of fibrosis.

Results: The results of WB and immunohistochemical staining of pancreatic tissue showed that SIRT3 was significantly reduced and the level of acetylation was significantly increased in CP. We subsequently treated human pancreatic stellate cells (HPSCs) with either HKL or plasmid to overexpress SIRT3, or we used 3-TYP or siRNA to knock down SIRT3. The results showed that SIRT3 in HPSC was inversely proportional to the level of acetylation and the degree of fibrosis. In order to seek specific targets of SIRT3, we performed acetylation sequencing on pancreatic tissues of SIRT3 knockout and normal CP mice. Based on the sequencing results, the pyruvate dehydrogenase complex(pdhx) was identified and deacetylated at lysine 189. Convincingly, we also confirmed the above results by co-immunoprecipitation and immunofluorescence double-label staining. Finally, we generated pdhx knock-in mice carrying an acetylation-defective lysine to arginine K194R mutation (pdhx^{K194R}), which showed reduced pancreatic inflammation and suppressed pancreatic fibrosis.
Conclusion: In conclusion, our study revealed the role of SIRT3 and acetylation in CP, and identified specific targets for interactions between SIRT3 and pyruvate dehydrogenase complex.

Introduction: Sarcopenia, characterized by reduced skeletal muscle mass and function, is a significant complication in patients with chronic pancreatitis (CP) and associated with a poor clinical outcome. CP is a progressive fibro-inflammatory disorder of the pancreas that affects both endocrine and exocrine pancreas.

While mechanisms underlying sarcopenia have been explored in elderly and cancer patients, understanding remains limited in chronic inflammatory disorders.

Aims & Methods: Our study aims to close this knowledge gap by comprehensively investigating the extent of sarcopenia in different experimental CP models, while elucidating the cellular mechanisms involved.

CP was induced in male C57BL/6 mice using three strategies: 1) by repetitive injections of caerulein over a period of 10 weeks, 2) ligation of the pancreatic duct, or 3) utilizing a knock-in mouse model carrying a heterozygous mutation in the cationic trypsinogen (T7D23A) which induces endogenous trypsinogen activation. PBS injected or sham operated mice served as controls.

To assess changes, we measured muscle diameter via HE-stained sections and MR-imaging, and evaluated muscle strength using grip force measurements.

In muscle lysates, we analyzed the expression levels of TGF- β superfamily members such as activin A, myostatin, and follistatin, along with E3 ubiquitin ligase RING-finger protein-1 (MuRF1), using both, qRT-PCR and immunoblotting techniques. Additionally, myogenesis factors in muscles as well as in vitro in C2C12 myotubes treated with activin A were investigated using qRT-PCR. Myotube diameters were measured after immunofluorescence staining of myosins. Moreover, activin A treated C2C12 myotubes, were assessed on proteasome expression analyzing α 4, rpt6 and LMP7 subunits and chymotrypsin-like activity via native PAGE and fluorogenic substrate activity assay.

Results: Reduced skeletal muscle size and strength were observed in the caerulein injection and pancreatic duct ligation model, while no reduction was determined in T7D23A mutant mice.

A decline in muscle diameter and force coincided with elevated levels of activin A, myostatin and MuRF1, accompanied by a simultaneous reduction in follistatin expression. In contrast, the expression levels of activin A, follistatin, myostatin, and MuRF1 remained unaltered in the muscle tissue of T7D23A mutant mice.

Stimulation of C2C12 myotubes with activin A for 48 h led to a significant reduction in muscle diameter compared to untreated cells and mRNA expression of key myogenesis factors such as myocyte-specific enhancer factor 2c (MEF2C), myogenic factor 3 (MyoD), and myosin heavy chains of fast muscle fiber type (MYH 1 and MYH 2) significantly decreased in vitro and in vivo.

Additionally, activin A increases the chymotrypsin-like activity and abundance of proteasomal subunits α 4 and rpt6 in a concentration dependent manner. Stimulation kinetics over 24 h revealed a dip after 4 h and significantly increased peak activity after 8 h und 12 h. Moreover, LMP7 was elevated, suggesting the formation of the immunoproteasome in vitro.

Conclusion: Signs of sarcopenia emerge in experimental CP models. Their onset appears to be associated with an activation of the activin receptor signaling pathways. These findings improve our mechanistic understanding and suggest potential biomarkers for sarcopenia. Furthermore targeting the TGF- β signaling cascade may be a promising therapeutic approach for sarcopenia in CP.

Introduction: Diagnosis of early chronic pancreatitis remains a challenge due to the limitations of current diagnostic techniques. Therefore, finding biomarkers that allow detection of the disease in early stages is necessary. In this regard, pancreatic juice is the ideal source of information and together with high-throughput techniques such as proteomics makes it possible to identify specific diagnostic candidates of early chronic pancreatitis.

Aims & Methods: The aim of the present study is to identify specific biomarkers for the diagnosis of ECP in PJ using proteomic techniques.

Exploratory, prospective, observational and descriptive study. A total of 32 patients were included: 11 healthy controls, 12 early chronic pancreatitis and nine chronic pancreatitis, according to Rosemont criteria (0-2, 3-4 or ≥ 5 , respectively; CAEIG 2018/537). Endoscopic pancreatic function test was performed by intravenous administration of 0.2 μ g/kg secretin, obtaining pancreatic juice samples at 15, 30 and 45 minutes.

Qualitative proteomic analysis was performed using a data-dependent acquisition (DDA) and quantitative analysis was carried out by sequential

window acquisition of all theoretical fragment ion mass spectra (SWATH-MS, DIA). For statistical analysis, log2FC was calculated with the mean or median. Significant differences between groups were assessed using the Mann-Whitney U-test or Student's t-test. Proteins with p-values <0.05 and log2FC $\geq$ +0.585 and $\leq$ -0.585 were selected.

Results: Twenty-three proteins were identified exclusively in patients with early chronic pancreatitis. In addition, quantitative analysis revealed 27 downregulated and 83 upregulated proteins compared to the other groups. These proteins are involved in nucleic acid regulation, signal transduction, cell communication, metabolism and energy pathways. Moreover, analyzing early chronic pancreatitis and chronic pancreatitis together, 54 unique proteins were observed. When comparing early chronic pancreatitis and chronic pancreatitis to healthy controls, 72 downregulated and 38 upregulated proteins were identified. Signal transduction, cell communication, metabolism, energy pathways, acid nucleic regulation, cell growth and/or maintenance and protein metabolism are the most related biological processes.

Conclusion: Proteomic characterization of pancreatic juice detected qualitative and quantitative differences both in chronic pancreatitis and early chronic pancreatitis, and also specifically in early chronic pancreatitis patients compared to healthy controls. These proteins might be potential biomarker candidates of early-stage disease. Moreover, these chronic pancreatitis-specific biomarkers could be potentially detected in more easily accessible human biofluids.

Introduction: The incidence of acute pancreatitis is rising globally and current studies show that around one in four acute pancreatitis cases labelled as idiopathic are of biliary etiology¹. As a cause of biliary pancreatitis, microlithiasis and sludge play a decisive role alongside classic gallstones².
